## WATER BALANCE IN SURGERY

WALTER G. MADDOCK, M.D.

AND

FREDERICK A. COLLIER, M.D.

ANN ARBOR, MICH.

The importance of water to the human organism is greater than that of any other substance. It normally comprises 65 per cent of the total body weight and is fundamentally concerned with every physiologic process. For centuries the intake and output of fluids have been investigated by man, the observations of Sanctorius,<sup>1</sup> published in 1614, on the perspiratio insensibilis of water from the skin and lungs being classics of early scientific endeavor.

Rowntree<sup>2</sup> and, more recently, Underhill<sup>3</sup> have presented reviews of the literature on water metabolism. Basic studies on an accurate measurement of the water balance of human beings have been carried out by Newburgh and his associates<sup>4</sup> and we acknowledge the inspiration and counsel given by this investigator.

From the surgical aspect, water balance becomes most important in dealing with the patient who, because of his disease or treatment, cannot take in sufficient fluids by mouth to care for his needs. Water must then be supplied by the physician, and, while experience has been a fairly reliable teacher as to the amount of fluid to give, it was apparent to us that the handling of the water requirements of the sick patient by figures based on facts would be of merit.

Accordingly, during the past four years a series of investigations on the water exchange of surgical patients under the various conditions of disease and treatment has been carried out. Before presenting the significant results of these studies, a brief review of normal water exchange is in order.

### NORMAL WATER EXCHANGE

Under conditions of health a nice adjustment between available and excreted water results in the maintenance of the water content of the body at a fairly constant level. The components of this water exchange can be listed in table 1.

From the Department of Surgery of the University of Michigan Medical School.

H.: *A Method for the Determination of Heat Production Over Long Periods of Time*, *ibid.* 10: 703 (Oct.) 1931.

Fluids drunk vary from about 800 to 2,000 cc. daily, the higher intakes usually occurring in hot weather when the vaporization loss is great. Water becomes available from food whether it is that of the diet or body material burned for energy. Food eaten generally furnishes more water than is commonly thought. In the first place, its water content will average close to 70 per cent of its total weight and, in addition to this, water is formed when the constituent proteins, fats and carbohydrates are oxidized for energy. From the two sources, each gram of solid food eaten furnishes approximately 0.9 Gm. of water, the total thus available from a routine maintenance diet amounting to from 1,000 to 1,500 Gm. daily. Even in starvation up to 500 Gm. of water daily becomes available from body materials used for energy.

On the excretory side, water lost in feces is generally insignificant compared to the loss through other channels. Body economy is shown here by the fact that although from 7 to 10 liters of fluid is poured into the upper half of the gastro-intestinal tract daily by various glandular mechanisms,<sup>2</sup> most of the water is absorbed in the lower part of the bowel and less than 150 cc. is lost with the stool.

Important water excretions are concerned with two physiologic processes; namely, the output of waste materials in solution through the kidneys, and the dissipation of body heat by the vaporization of water from the lungs and skin. The vaporizing process plays an important part in the control of body temperature and is a continuous process in that there is always some moisture in the breath and also on the surface of the body, even without activity by the sweat glands. Ordinarily a person likes to keep himself comfortably cool and avoid sweating. Under such circumstances Newburgh and his associates have established the constancy of approximately 25 per cent of body heat being dissipated by water vaporized, and from a determination of the exact amount of water so used have been able to calculate the daily caloric expenditure of individuals under routine activities.<sup>4b</sup> At the 25 per cent rate a group of their subjects was found to disperse from 1,000 to 1,500 Gm. of water daily. The remaining 75 per cent of body heat is dissipated by radiation, conduction and convection from the body surface. These later processes become much less effective as the environmental temperature increases and greater percentages of heat are then dispersed by vaporization, the sweat glands pouring water on the surface of the body for this purpose. Vaporization can well be regarded as the safety factor in heat dissipation, since without its action many of the higher environmental temperatures would be intolerable.

It is important to point out that the vaporizing process, in contrast to water for kidney function, is

little affected by the amount of water available. There is no mechanism whereby, when the water supply is low, temperature can be kept within normal limits with the use of less water than usual. The vaporizing process may be regarded as having "preferential rights" on available water over that of the kidneys. In deprivation of water for long periods of time the urine output may drop to almost nothing, the skin becomes hot and dry, and insufficient water may be used to keep internal body temperature within normal limits; but water still continues to be vaporized from the skin and lungs, with dehydration increasing until death occurs.

On the other hand, the kidneys are markedly affected by the amount of water available and excrete the waste materials presented to them with the water left after the other processes have been cared for. Thus one finds large daily urine volumes of low specific gravity and small daily volumes of high specific gravity. With a good supply of available water from fluids drunk and food eaten the balance between the intake and the output of fluids is largely maintained by the kidneys using the surplus water. On this basis a good fluid intake is shown by a good urine output and a small urine volume of high specific gravity practically always means insufficient water.

With regard to the surgical patients, the data and conclusions from the study of this group can be presented from the fairly definite points of view of dehydration attendant on surgical operations, the daily water losses of surgical patients, the water balance of the dehydrated patient, and parenteral fluids.

#### DEHYDRATION ATTENDANT ON SURGICAL OPERATIONS

It is common knowledge that on the day of a major operation a low intake of fluids and food by most surgical patients decreases their supply of available water. The exchange for that day is further interfered with by the frequent occurrence of abnormal fluid losses. The purpose of our first investigation<sup>5</sup> was to determine these losses quantitatively when they seemed to be greatest; that is, in the warm operating room and the

immediate postoperative recovery period of four hours, when the patient is bundled up in extra blankets and frequently perspires profusely.

A group of eighteen patients undergoing a variety of general surgical operations was studied. The loss of fluid in the operating room by vomiting was insignificant. The blood loss was usually much greater than the amount estimated by the operating surgeon, a few of the volumes obtained being given in table 2. In general, the blood losses were greater when large areas were exposed and there was more or less continuous oozing of blood than with hemorrhage from spurting vessels.

The greatest fluid output during the operative and four hour postoperative period was generally the vapor-

ization loss. This made up 700 cc. of the average of 1,000 cc. lost by blood, vomitus, urine and vaporization during this time. It was learned that this sweat loss could be appreciably reduced if the extra blankets of the old fashioned postoperative "ether bed" were done away with and the patient was simply transferred from the operating table to a bed with only the usual amount of covers but warmed with hot water bottles. Water needlessly excreted was thus saved and the urine output showed a corresponding increase in amount. The reduced covers have been adopted as a routine in our postoperative surgical care. Patients are no longer

found weighed down with a mass of covers and sweating as if in a Turkish bath. There has been no increase in postoperative pulmonary complications with the new arrangement, and the patients are infinitely more comfortable.

As a result of the restriction in fluid and food intake and the increased fluid losses, most patients dehydrate to some extent on the day of their operation. The plan of many surgeons of giving some fluids parenterally on this day, particularly to patients undergoing long, serious operations, is well founded. For the general run of cases, however, the dehydration is not severe and with the improvement of the first and second postoperative days a greater ingestion of fluid returns the water exchange to normal. Occasionally nausea and vomiting interfere with the ingestion of water from the gastro-intestinal tract, or throughout the period of the disease or treatment rest of the gastro-intestinal tract is desired. Fluids must be given parenterally to these patients and the physician can provide the proper amount only if he knows what daily fluid losses must be cared for. Our second study of water exchange<sup>6</sup> was to furnish data in this regard.

#### THE DAILY WATER LOSSES OF SURGICAL PATIENTS

As in the healthy adult, the excretion of water by the surgical patient is mainly for two normal functions: the carrying away of waste materials through the kidneys, and the dissipation of body heat. The loss of water in the stools is generally insignificant in surgical conditions and can be disregarded. Since the vaporizing process seems to have first claim on the available water and the kidneys function largely with what is left, our first problem was to learn what the vaporizing loss amounted to in a group of representative patients. Briefly, the method for this determination was as follows: The patient, transferred from his bed to a Bradford frame, was picked up and weighed at 8 a. m. The weight of all ingesta and excreta up to 8 a. m. the following morning was obtained, at which time the

6. Collier, F. A., and Maddock, W. G.: The Water Requirements of Surgical Patients. *Ann. Surg.* 94:932 (Nov.) 1933.

patient was again weighed. The total insensible loss of weight for the twenty-four hour period was calculated by the following equation: Beginning weight — (end weight — ingesta + excreta).<sup>4b</sup> This total insensible loss is the result of the continuous vaporization of water from the skin and lungs and the respiratory exchange of carbon dioxide for oxygen. Water usually comprises more than 90 per cent of the insensible loss, so that for our purposes the consideration of the latter as entirely water loss occasioned little error.

Adult surgical patients convalescing smoothly from major operations were found to vaporize from 1,000 to 1,500 cc. of water daily. Two children weighing about 60 pounds (27 Kg.) each vaporized 850 cc. daily under similar conditions. This is the same amount that these individuals would vaporize when up and about at normal routine activities without sweating.

Several conditions encountered in surgery increase the insensible loss of water. A warm, moist skin is a common clinical observation in patients with hyperthyroidism. Several individuals with this disease were found to vaporize from 1,500 to 2,000 cc. daily.<sup>7</sup> This increase over the normal of from 1,000 to 1,500 cc. was not found to result from any abnormal process of heat dissipation associated with hyperthyroidism but was simply due to the fact that, with more heat to dissipate, more water was used for this purpose.

Fever is a common complication among sick surgical patients and is one in which, because of the increased heat production and active sweating, the vaporization loss would be expected to be increased. Such was found to be the case in the study of several patients with infections. Water vaporized varied from 1,500 to 2,500 cc. daily. In general, for the sick surgical patient water for vaporization can be safely estimated at 2 liters a day.

With this figure for vaporization at hand, water for urine is the next problem. The amount available should be sufficient to permit the kidneys to excrete the waste materials presented to them without having to work at

urine a day for normal function. With a twenty-four hour urine output appreciably less than this, retention of waste materials can be looked for, and the blood nonprotein nitrogen will generally be found elevated. With diseased kidneys, more than 500 cc. of urine daily is needed, the required volume increasing as the concentrating ability decreases. In instances of the most severe renal damage, in which the kidneys can concentrate urine to a specific gravity of only 1.014 to 1.010, the figures show that close to 1,500 cc. of water is required. A minimum output, then, of 1,500 cc. of urine daily will take care of the excretion of waste materials by kidneys of all ranges of function, and this is the amount allowed for urine in our estimations of

TABLE 4.—Water Needed for Excretions

3. Abnormal losses of water—vomitus, and so on.....	.....
Total.....	3,500 cc.

water requirements. Larger urine volumes, particularly in instances of infections of the urinary tract, are often desirable.

Frequently abnormal losses of fluid have to be considered in the water exchange of the sick surgical patient. Blood, vomitus, drainage from intestinal and biliary fistulas, diarrhea, massive exudation from inflamed surfaces, and sometimes sputum may remove important amounts of water and materials from the body. Such losses are "absolute losses" in that they carry out no physiologic function and take water that is needed for normal processes. The amount of these abnormal losses, by actual measurement or estimation, should be recorded on the patient's record by the nursing staff, so that they can be included in the calculations of water requirements.

When a patient is taking nothing by mouth, the only water available daily to care for the excretions, without producing dehydration, is that coming from body glycogen, fat and protein burned for energy. This source seldom furnishes more than 500 cc. daily, and the amount can well be forgotten in the calculations of water to be given to the sick patient, thus having a little *extra supply*. The excretions are the factors to care for in maintaining body fluids, and these can be summarized as in table 4.

If the patient is taking some fluid by mouth, that amount can be deducted from the 3,500 cc. total. If abnormal losses are occurring, they should be added, since with a failure to do so the seemingly sufficient 3,500 cc. total may be entirely inadequate. The surgeon who is quick to recognize the signs of dehydration in a patient seen for the first time may overlook the same signs when they occur in a patient he is seeing every day and who is receiving apparently a good supply of water but is actually dehydrating because of abnormal fluid losses. The resulting poor output of urine is often erroneously attributed to a reflex or toxic suppression of kidney function, whereas the real fact is that the patient has not been given sufficient water. This point cannot be too strongly emphasized.<sup>9</sup> There are many causes of anuria, but no others should be considered until the water exchange of the few previous days has been checked over and dehydration as the etiologic factor has been eliminated.

TABLE 3.—Minimum Amount of Water Needed to Excrete 35 Grams of Waste Material

	1.024-1.029	605
	1.019-1.015	850
	1.014-1.010	1,139

their maximum capacity. For the sick surgical patient we believe this to mean an output of at least 1,500 cc. of urine daily.

This volume was selected purely on a consideration of kidney function. Lashmet and Newburgh<sup>8</sup> determined the excretory capacity of normal and abnormal kidneys under conditions forcing them to work at their maximum concentrating ability. Figures on the minimum amount of water needed to excrete 35 Gm. of waste materials, a fair daily amount, were calculated from their data and are given in table 3.

From these figures it is evident that an individual with normal kidneys needs to excrete about 500 cc. of

## WATER BALANCE OF THE DEHYDRATED PATIENT

Patients who enter the hospital in a dehydrated condition present an additional problem in water balance.<sup>10</sup> An amount of water sufficient to maintain body fluids is not enough for them, but an additional amount is necessary to restore the body water previously lost. If one knew how much fluid had been previously lost, water for its restoration could be given in a quantitative fashion similar to water for the maintenance of body fluids. There are no quantitative tests to show the degree of dehydration, so the only answer to the problem seemed to be a determination of the amount of

TABLE 5.—Amounts Equaling 6 per Cent of Various Body Weights

Body Weight	6 per Cent
10 Kg., or 22 lbs. ....	600 cc.
20 Kg., or 44 lbs. ....	1,200 cc.
60 Kg., or 132 lbs. ....	3,600 cc.
80 Kg., or 176 lbs. ....	4,800 cc.

water individuals need to lose in order to show the common clinical signs of dehydration, and then to provide that amount of additional water when patients are seen with those signs.

To furnish data in this regard, two normal subjects were fed a dry maintenance diet for a number of days, during which time they were dehydrated by the withholding of water until the beginning signs of serious dehydration appeared; that is, a dry hot skin, a dry tongue, sunken eyes, a little fever, and a urine output insufficient to excrete the normal waste materials. The last mentioned was the only readily measurable sign and was used in such a way that the dehydration of both subjects was continued until their blood non-protein nitrogen had increased to a little above 40 mg. per hundred cubic centimeters. When this occurred, all the common clinical signs of dehydration mentioned were well established. As evidence of the adverse conditions under which the kidneys were working the urine of the 26 year old subject finally reached a specific gravity of 1.041 and contained a trace of protein and more than the usual number of casts and erythrocytes.

The water balance data of both subjects showed that the signs of serious dehydration produced were the result of being depleted of an amount of water equal to approximately 6 per cent of their body weight. Observations by several members of the investigating staff during the past four years support the opinion that, when the signs of serious dehydration are present in a patient, body fluids of an amount equal to at least 6 per cent of the patient's body weight have been lost. The figures in table 5 show what this amounts to for individuals of various weights.

While we know that these volumes of fluid are called on in emergencies, it is not practical to regard them as a true reserve of fluid, since beyond the first few hundred cubic centimeters they are given up with increasing reluctance and to the detriment of the whole organism. For children the relatively small amount of fluid that represents 6 per cent of the body weight probably accounts for the rapidity with which, under adverse conditions, they become sick and dehydrated.

When water was again given to our experimental subjects the urine volume did not immediately increase

but nearly all the first day's water intake was retained to replace the body fluid previously lost. It was perfectly apparent that the major need for water was to restore to normal some of the internal chemistry that had been upset during the dehydration period. Water to relieve dehydration and water for vaporization was decidedly more important than water for kidney function, and it was only when the former had been cared for that sufficient water became available for urine.

In considering the water requirements of a 60 Kg. patient who enters the hospital with the beginning signs of serious dehydration well established, a calculation of the amount of fluid to give during the first twenty-four hours should include the factors given in table 6. This is a lot of fluid, but studies by us on several dehydrated patients have shown that such quantities are necessary to provide for the dehydration, for vaporization and abnormal loss, and then to have enough water left for kidney function. Of course, once the depleted fluids have been taken care of, much less water is needed to maintain normal fluid exchange. Besides seeing to it that sufficient fluids are provided, a quantitative consideration of the water requirements of the sick surgical patient will also avoid the administration of too much fluid.

## PARENTERAL FLUIDS

So far, the quantity of fluid to be given parenterally in order to maintain body fluids or treat dehydration has been considered. The kind of fluid to give also merits some thought.

The fundamental proposition back of the choice of fluid is that of supplying as nearly as possible what the patient needs. There is no question that some dextrose should be given to all patients requiring water parenterally. It is an ideal fuel for energy, it prevents or relieves ketosis, and it protects the liver. In contrast to dextrose, the indications for the administration of sodium chloride are not quite so simple.

4. Water to restore depleted fluids, 6 per cent of 60 Kg. ....	3,600 cc.
Total.....	7,100 cc.

The excellent observations of Hartwell and Hoguet,<sup>11</sup> Orr and Haden,<sup>12</sup> McIver and Gamble<sup>13</sup> and Hartman and Elman<sup>14</sup> have firmly established the value of saline solutions in replacing the sodium chloride depletion associated with the loss of secretions from the gastrointestinal tract. A distinct tendency exists, however, for the routine use of saline solutions for all parenteral administrations of fluid, without regard to whether sodium chloride is needed or not. Matas<sup>15</sup> in 1924 pointed out the serious drawbacks of such a plan, emphasizing in particular the occurrence of degenera-

tive changes in heart muscle and kidneys, and edema of the lungs. Edema is not uncommonly seen among surgical patients receiving fluids parenterally. Jones and Eaton<sup>16</sup> presented a review of thirty-four such cases and emphasized the predisposing factor of under-nutrition as shown by low total serum proteins and serum albumin. Other factors, such as the excessive administration of water and salt, profuse surgical drainage and the general effects of sepsis, were also pointed out. These factors are commonly present in seriously ill patients, and it is often to just these individuals that the parenteral administration of fluids is so necessary and valuable.

From clinical observations it had been our impression that, while many conditions predisposed to the retention of water in sick surgical patients, the precipitating factor was frequently the indiscriminate use of saline solutions. Largely to corroborate this opinion, a study was made of the water exchange of three groups of such patients,<sup>17</sup> each receiving approximately 3,500 cc. of one of the commonly used intravenous fluids daily for several days as a part of their necessary postoperative care.

The first group was given 5 per cent dextrose in physiologic solution of sodium chloride. All of them retained water and gained weight, one developing edema of the lower part of the back and of the ankles. When the intravenous solution was changed to 5 per cent dextrose in distilled water the retained water was promptly given up. This finding is worthy of special emphasis. It was not necessary to limit the administration of water to these patients or to use diuretics to get rid of the edema fluid; the stopping of the sodium chloride was all that was necessary.

The importance of poor general condition to water retention was brought out by the fact that five patients convalescing nicely from the treatment of surgical lesions and whose general condition was excellent did not retain water when given 5 per cent dextrose in physiologic solution of sodium chloride for several days. One of them had previously retained water when given this solution at the time of having a moderately severe systemic reaction from an acute pyogenic infection about the elbow.

The second group of seven sick patients was given 5 per cent dextrose in Ringer's solution. Six of the seven retained water, but it was our impression that the amount retained was a little less than that of the group receiving 5 per cent dextrose in physiologic solution of sodium chloride. This apparent advantage of Ringer's solution over physiologic solution of sodium chloride may be due to the small amount of potassium chloride and calcium chloride present in the former. Ringer's solution is now our fluid of choice for patients needing sodium chloride.

The third group of sick patients received 5 per cent dextrose in distilled water. None of them retained water, their exchange being approximately the same as if the solution had been given by mouth. As was expected from clinical observations, with no abnormal loss of sodium chloride the plasma carbon dioxide combining power and chlorides of these patients did not change materially when given the dextrose in water for

six days. One has no need to worry about washing salt out of the body with such treatment.

Considering that twelve out of the thirteen sick patients receiving 5 per cent dextrose in saline solutions retained water, it is apparent that warnings concerning the development of edema with the indiscriminate use of sodium chloride solutions are well founded. We believe that the only reason why edema is not more frequently seen with such treatment is that the solutions are generally given for only a day or two. While edema developed in only one of the patients studied, in several of them it was well on the way to do so and would have if the solutions had been given for a few days longer. Waterlogged tissues are often seen in surgical patients coming to autopsy. Undoubtedly an excess of salt solution is a contributing factor in some instances. The first question in the mind of the surgeon on finding edema in a patient who has been receiving fluids parenterally should be "How much salt solution has been given?"

It is difficult to lay down hard and fast rules to cover the proper administration of saline solutions to all patients. Recently the reasons for the giving of parenteral fluids to 100 general surgical patients at the University Hospital were analyzed.

Twenty per cent of them had been vomiting and needed some sodium chloride besides water and dextrose. Ringer's solution was given here, but not too much of it. To avoid the administration of excessive amounts of salt, two procedures can be followed: Patients with a considerable loss of gastro-intestinal secretion, particularly those in whom the loss has occurred before admission to the hospital, so that consequently little is known about it, should have a blood chloride and a carbon dioxide combining power study done to show the depletion of chloride and basic ions respectively. If these are found to be low, from 1,500 to 2,000 cc. of Ringer's solution can be given daily. The blood chemistry studies should be repeated every two days while the salt solution is being given, so that it can be stopped when these electrolytes are up to normal. Since the loss of one of these electrolytes is usually greater than the other and the replacement of one is therefore needed more than the other, chlorides in alkalosis and sodium in inorganic acidosis, it is desirable to alternate the saline solution liter for liter with 5 per cent dextrose in water during the correction period. This provides an immediate excess of water, and with this the kidneys can generally be relied on to excrete the less needed electrolyte. Alkalosis and acidosis can thus be taken care of with the same solutions.

The second plan is applicable when the patient is in the hospital and the loss of gastro-intestinal secretion, as by vomiting, has been measured. It is satisfactory then to give parenterally an amount of Ringer's solution equal to the amount of vomitus. The concentration of sodium chloride in this solution (or in physiologic solution of sodium chloride) is always greater than that in vomitus or other secretions of the gastro-intestinal tract.<sup>18</sup> With such a procedure the electrolyte loss is well taken care of, and the mistake of giving close to 30 Gm. of sodium chloride, the amount present in 3,500 cc. of physiologic solution of sodium chloride or Ringer's solution, to cover the 5 Gm. loss of sodium chloride in a liter of vomitus, is avoided.

That sodium chloride is not needed as a routine was shown by the fact that 80 per cent of the patients

16. Jones, C. M., and Eaton, F. B.: Postoperative Nutritional Edema, *Arch. Surg.* 27: 159 (July) 1933.

17. Coller, F. A.; Dick, V. S., and Maddock, W. G.: The Maintenance of Normal Water Exchange with Intravenous Fluids, *J. A. M. A.* 107: 1522 (Nov. 7) 1936.

18. Dick, U. S.; Coller, F. A., and Maddock, W. G.: Data to be published.

analyzed were given fluids parenterally simply because through their disease or treatment they were unable to take sufficient fluids by mouth to maintain a normal balance. These patients had not been vomiting and were not dehydrated. What they needed was sufficient water daily to provide for their normal excretions, and enough dextrose to prevent ketosis. Throughout the study of the sick patients receiving fluids intravenously the suitability of 5 per cent dextrose in distilled water for furnishing enough dextrose and maintaining a normal water exchange was apparent.

Concerning the mechanics of giving fluids parenterally, the intravenous route has been preferable in our hands to subcutaneous infusions. The main apparatus consists of a 700 cc. containing bottle, a drip tube, and pure gum rubber tubing throughout. Intravenous canulas have seldom been employed, it being our experience that phlebitis was more common with them than with ordinary intravenous needles, the site of which is changed daily. The rate of flow is never faster than 500 cc. an hour. This permits the administration of a good volume of fluid in a few hours during the daytime, if possible, so that the night is left undisturbed for rest and sleep. At the same time, with this rate there is no possibility of overloading the heart. No particular effort is made to keep the intravenous fluid at a constant temperature during its administration, since this factor is apparently unimportant when the fluid is given slowly.

#### COMMENT

There are many questions on water balance and parenteral fluids in relation to surgical patients that have not been answered in this paper. The problems studied have been interesting and the data obtained have had gratifying clinical applications. The whole subject forms an important chapter in preoperative and postoperative care, and its skilful handling often saves the life of the seriously ill patient.

University Hospital.

#### ABSTRACT OF DISCUSSION

DR. LEONARD G. ROWNTREE, Philadelphia: Everything that the authors have said constitutes sane and safe advice in relation to the handling of the surgical patient from the standpoint of water. Two thirds of the human body is composed of water, and consequently the water balance is of tremendous significance to the proper functioning of the organism under all conditions. During and after surgical intervention there is often a tremendous strain on the organism, and the importance of water is greatly enhanced. Urologists work mostly with the kidney and the urinary system, which is concerned with the excretion of water and water soluble substances that are carried off as waste material. I have always been interested in the urologic point of view in relation to excretion by the body. I have often wished that I could go back twenty years, or preferably thirty, and grasp at an earlier date the possibilities that urology has to offer relative to failure of excretion and the development of disease. The kidney is responsible to a large extent for what Cannon has termed homeostasis; that is, keeping the blood constant in volume and composition, a condition essential to optimum efficiency. In this connection one has to consider not only the side of homeostasis in keeping the blood pure but that which has been emphasized this afternoon and was formerly emphasized by Claude Bernard, "the volume obligatoire"; that is, a sufficient quantity of urine for the complete solution of the waste products of metabolism. What happens at the time of operation? Water is withheld before and after operation. This is necessary from the standpoint of the intestinal tract, but water should not be withheld from the body as a whole. The night before an operation,

the patient is usually given a dose of some purgative, frequently castor oil. The figures that the authors have given appear rational: 3.5 liters a day for a patient who is not dehydrated and 7 liters a day for the patient who is dehydrated and in whom the depots of water in the body have been exhausted. These figures can serve only as guides and not as fixed rules. I believe it would be a mistake to restrict fluids to 5 per cent dextrose. There are many instances in which other substances, particularly electrolytes, are essential. These should be supplied to meet the individual needs. One can overdo this water business and produce water intoxication. Attempts have been made to devise a test whereby one can tell whether or not the water need is great in an individual. The disappearance of McClure's saline "bleb" has been suggested.

DR. A. J. SCHOLL, Los Angeles: Maddock and Coller's paper and Dr. Rowntree's discussion, with their previous papers, have covered almost all there is to say about water balance. For years physiologic solution of sodium chloride has been used almost universally following operations, 3,000 and 4,000 and sometimes 5,000 cc. a day. The authors stated that in twelve out of thirteen of their cases a retention developed when saline solution was given daily for more than three or four days. Keith has recently shown that it is not the chloride but the sodium radical that causes the retention. If the sodium is changed to potassium, retention does not occur; there may be a diuresis. Keith states that as yet he is not ready to recommend the use of the potassium salt, but patients such as the authors discussed do not need the potassium any more than they need the sodium or chloride; what they need is simply more fluids. Of course, in an occasional case, after vomiting or after excessive sweating, there is a loss of body chlorides and it must be replaced. Thirty years ago the farmers in California found that if they drank salted oatmeal water they were less liable to have heat exhaustion and that they were better able to go through the heat of the day. They did not know what the oatmeal water did, but it kept them from becoming exhausted in the heat. During the building of Boulder Dam the heat at the base of the canyon was terrific. There were days when the thermometer registered from 110 to 115 F. in the base of the river bed. The men drank prodigious amounts of water; 10, 15 or 18 liters a day was common. They came out of the canyon cooled off, and the salt from their sweat crystallized on their faces and on their arms like frost on a window. Heat exhaustion was common until it was suggested that salt be added to the drinking water; after that the men could get only salt water to drink. This addition of salt to their water practically stopped the occurrence of heat exhaustion.

DR. WALTER G. MADDOCK, Ann Arbor, Mich.: I thank Dr. Rowntree and Dr. Scholl for emphasizing the important points in their discussion. The administration of too much water occasionally occurs. While a thoughtful consideration of water exchange is largely important in seeing to it that the patient receives sufficient water, it also serves to prevent the giving of too much fluid. My plea is for not too much fluid or too little fluid, but the correct amount, and it can be calculated. As has been stated, the question of whether to furnish sodium chloride along with water and dextrose to patients requiring parenteral fluids must be decided on a consideration of the needs of each individual patient. A routine procedure will fail to take care of the important exceptional case. In my hands the administration of parenteral fluids with due regard to both the amount and the kind of fluid to give has yielded gratifying results.

**Croup in Childhood.**—Croup, however, is not a disease but a symptom, and the practitioner must determine the underlying pathology. The conditions which give rise to croups are congenital laryngeal stridor; laryngismus stridulus; laryngitis stridulosa; acute laryngitis, diphtheritic laryngitis; retropharyngeal abscess; papilloma of the larynx, or upper trachea. Not all of these conditions have a surgical bearing so far as treatment is concerned, but each of them must be considered in making a diagnosis.—Crooks, James: *Surgical Aspects of Croup in Childhood*. *Practitioner* 137:769 (Nov.) 1936.

## THE PATHOLOGIC CHANGES RESULTING FROM VITAMIN DEFICIENCY

S. B. WOLBACH, M.D.

BOSTON

Descriptive accounts of the pathologic changes resulting from each vitamin deficiency would make a voluminous report, dry and nonstimulative. The subject will be presented with the attitude that each deficiency causes distinctive functional disturbances and is accompanied by distinctive morphologic changes which together may reasonably be regarded as primary effects. In consequence, it is assumed that some of the general disturbances in nutrition, blood formation and growth, common to several of the vitamin deficiencies, are in all probability secondary nonspecific effects. The primary morphologic effects, as far as known, when analyzed all prove to be manifestations of retardation or suppression of normal processes. In recovery from a vitamin deficiency following restoration of the vitamin to the diet, normal morphologic sequences are resumed and proceed for a brief period at a rate exceeding the normal, until repair is completed. Possibly physiologic activities of certain types may be suppressed without demonstrable tissue or cytologic effects occurring. In the search for initial specific morphologic changes the pathologist has opportunity to make his humble contributions to the goal common to all biologic sciences—the understanding of the chemistry of living cells.

The pathologic or morphologic characterization of a vitamin deficiency involves a dual basis: (a) the changes in consequence of the deficiency, and (b) the changes accompanying recovery from the deficiency ending in restoration to normal structure.

## VITAMIN A DEFICIENCY

*Specific Pathology.*—The primary effect of vitamin A deficiency is on epithelial structures. The sequences are atrophy of the epithelium concerned and the substitution for it of a stratified keratinizing epithelium, identical in appearance in all locations, and arising from focal proliferation of basal cells. These sequences have been carefully worked out in rats<sup>1</sup> and guinea-pigs.<sup>2</sup> Since replacement by keratinizing epithelium in many organs has also been found in human infants,<sup>3</sup> in the monkey (*Macacus rhesus*)<sup>4</sup> and in the albino mouse,<sup>5</sup> and since gross changes indicate the same histologic changes in swine,<sup>6</sup> in dogs,<sup>7</sup> in rabbits,<sup>8</sup> in cattle,<sup>9</sup> and in the

domestic fowl,<sup>10</sup> the conclusion seems unavoidable that vitamin A is essential in most vertebrate species and that its withdrawal is followed by a common effect on epithelial structures. For convenience this change will be called keratinizing metaplasia, regardless of exact connotations of the term. The detailed studies by Howe and myself<sup>11</sup> have led us to the conclusion that the absence of vitamin A creates a starvation specific for many epitheliums. The consequence is atrophy, which progresses to a state wherein the cells, although having the appearances of viability, become inert in physiologic activities and in their rôle of covering membranes. An invariable sequence in pathology is that a break in the continuity of a tissue is followed by reparative proliferation. In vitamin A deficiency the basal cells normally concerned in maintaining the integrity of epithelium respond by active mitotic division. As the basal cells have a focal distribution in all nonstratified epitheliums, the next effect of the deficiency after atrophy is the appearance of scattered areas of proliferative activity beneath the original epithelium. The new (reparative) cells by their continued growth undermine and replace the original epithelium and, regardless of previous function and morphology of the region, develop into a stratified keratinizing epithelium. An important feature in explanation of much of the gross pathologic change is the fact that this replacement epithelium is identical in all locations and comparable in all its layers with epidermis. It has a continuous layer of basal cells—a stratum germinativum—in continuous proliferative activity while superficially it is continuously casting off keratinized cells. The striking gross pathologic condition of vitamin A deficiency in animals and in human infants is the outcome of the accumulation of keratinized epithelial cells in many glands and their ducts and in other organs. In glandular organs, cysts of considerable size are formed, filled with yellowish cheesy masses of keratinized cells. In the lungs of human beings as well as of experimental animals this process leads to cyst formation, bronchial occlusion, and consequences such as bronchiectasis and atelectasis. Early students of vitamin A deficiency, chemists and physiologists, neglected to study these cysts and believed them to be abscesses. Hence, for many years vitamin A was believed to protect against infection. As a matter of fact, the plugs of desquamated epithelial cells in ducts, bronchi and trachea, opening as they do on regions normally infected with bacteria, provide a culture medium for their growth. In spite of the fact that in both human beings and laboratory animals such bacterial growths were frequently found by us, very rarely was there invasion of the tissues, presumably because of the protection afforded by the stratified epithelium.

*Distribution of the Keratinizing Metaplasia.*—In the rat, the order of response to vitamin A deficiency by metaplasia is:

1. Salivary glands, including submaxillary, parotid and all accessory glands of the tongue, buccal cavity and pharynx.

2. Respiratory tract, including nares, maxillary sinuses, Jacobson's organ, trachea and bronchi.

3. Genito-urinary tract, including the renal pelvis, ureters, bladder, epididymis, prostate, seminal vesicles, coagulating glands, uterus, oviducts and accessory sex glands of the vulva.

4. Eye and parocular glands, including the corneal and palpebral conjunctiva and the harderian, intra-orbital and extra-orbital lacrimal glands and the meibomian glands.

In the guinea-pig, lesions of the conjunctiva and parocular glands did not develop in our experiments even though advanced lesions (keratinizing metaplasia and its consequences) were found in all other locations as recorded for the rat. A marked difference in behavior as compared with the rat was early and extraordinary degrees of metaplasia in the uterus and bladder.

In human infants, keratinizing metaplasia has been found in the conjunctiva, mucosa of the nares, accessory sinuses, trachea, bronchi, pancreas, renal pelvis, ureters, salivary glands, uterus, and periurethral glands. The commonest and earliest appearance of the metaplasia is in the trachea and bronchi. Next in frequency and sequence is the pelvis of the kidney. The early effect of the deficiency on the respiratory mucosa is a satisfactory explanation of the frequency, severity and persistence of the pneumonias that have been in most instances responsible for death in vitamin A deficient infants.

In the human being, as in the rat, involvement of the eye occurs late. The first change is metaplasia of the epithelium of the cornea and of the conjunctival sac. Atrophy and metaplasia of ducts of the parocular glands contribute to the consequences of the accumulation of keratinizing cells in the conjunctival sac. The cornea becomes vascularized, edematous and infiltrated with leukocytes. Infection of the cornea, favored by excessive accumulation of keratinized cells, may lead to ulceration of the cornea and hypopyon.

*The Teeth in Vitamin A Deficiency.*—The continuously growing incisor teeth of rodents—rats and guinea-pigs—are profoundly affected owing first to atrophy and metaplasia of the enamel forming organ and subsequently to atrophy and cessation of or irregular functioning of odontoblasts. Enamel formation is suppressed, and striking deformities of the dentin result.<sup>12</sup> May Mellanby<sup>13</sup> has summarized her work on teeth in an excellent review and presents convincing proof that absent or defective enamel and dentin formation are consequences of vitamin A deficiency.

Boyle<sup>14</sup> has described in the tooth germ of a human infant with vitamin A deficiency enamel organ changes comparable to those we have studied in rodent incisor teeth. In all probability, vitamin A deficiency, during the formative period of teeth, outranks all other vitamin deficiencies in importance.

*Secondary Effects of Vitamin A Deficiency.*—While the keratinizing metaplasia produces impressive gross lesions which are often the immediate cause of death, as in the lungs of infants and in experimental animals leading to complete suppression of urine by occlusion of ureters and renal pelvis, it must be remembered that it is a late effect of the deficiency; in fact, the

consequences of attempted repair following atrophy of essential epitheliums. The effects on the organisms as a whole which follow reduced activities of many epitheliums in earlier periods of atrophy preceding metaplasia replacement must be considered.

The secondary effects, common both to infants and to laboratory animals, are (1) loss of weight due largely to loss of fat in all storage depots, but also to atrophy of musculature and many organs which do not undergo keratinizing metaplasia, (2) anemia, (3) cessation of growth of bones, (4) degenerative lesions of skeletal muscle, and (5) lymphoid hypoplasia of the spleen.

The loss of fat in experimental animals in the absence of vitamin A takes place in spite of abundant fat in the diet, but this is also the case with other vitamin deficiencies accompanied by emaciation, notably the B<sub>2</sub> complex. The anemia in infants and experimental animals is accompanied by hemosiderosis in the spleen and liver and, finally, by atrophy of the spleen and bone marrow.

In animals, restoration of vitamin A to this diet is followed by regeneration of the bone marrow, disappearance of hemosiderin from the spleen and liver, and in the rat also in the spleen by an active hyperplasia of lymphoid tissue and an outburst of erythroblastic activity. Again, the anemia and hemosiderosis are not peculiar to vitamin A deficiency. Both occur in striking degree in animals in vitamin B<sub>2</sub> complex deficiency and in long continued partial vitamin C deficiency.

The cessation of growth of bone is due to cessation of proliferative activity of the epiphyseal cartilages. A narrow band of atrophic cartilage results, which becomes bounded by a thin plate of bone on the diaphyseal side. In recovery from vitamin A deficiency the cartilage regenerates, and blood vessels from the diaphyseal marrow penetrate the limiting bony plate, and normal endochondral bone formation is resumed. The effect on bone is that common to any atrepsia, of vitamin deficiency origin or otherwise.

The degeneration of skeletal muscle in vitamin A deficiency, while often very striking and even terminating in calcification, is also common to deficiencies of diverse causation.

Lesions of the nervous system, evidenced by degeneration of the myelin sheath, have been described by several workers, notably in swine, fowls and cows by Hughes and his associates,<sup>15</sup> in rats by Zimmerman<sup>16</sup> and Aberle.<sup>17</sup>

Recently, Edward Mellanby,<sup>18</sup> on the basis of studies of the trigeminal and a few other nerves by the capricious Marchi technic, suggests that the epithelial responses to vitamin A deficiency are secondary to lesions of afferent nerves.

Degeneration of the myelin sheath is common to so many disorders of man and animals as the result of several vitamin deficiencies and divers causes that very careful work will be required to establish a specific relationship of its presence to vitamin A deficiency.

For the present it seems logical to regard the lesions of the nervous system as among the late secondary consequences of vitamin A deficiency.

*Repair in Recovery from Vitamin A Deficiency.*—The lesions of vitamin A deficiency, uncomplicated by destruction of tissue by infectious process, disappear rapidly after restoration of the diet. In rats, gain in weight, resumption of growth in bones and teeth, and regeneration of the bone marrow and spleen become apparent in from six to eight days. Reparative changes in the metaplastic epithelium begin as early as the fifth day. The initial changes are separation of superficial keratinized cells and vacuolization of cells of intermediate layers. The epithelium becomes divided into two zones by further vacuolar degeneration and leukocytic infiltrations. The superficial zone of cells degenerate, the deep zone, consisting of the lowermost layers of cells corresponding to the stratum germinativum of the epidermis, survives and the cells proceed to differentiate into the type of epithelium originally present. On the whole, the change back to the normal epithelium is an abrupt one and affords further evidence that the primary consequence of vitamin A deficiency is epithelial and not of nervous origin. This reparative sequence of the epithelium has its normal counterpart in changes in the vagina of rodents during that part of the estrous cycle in which the cornified vaginal mucosa returns to the mucous type.<sup>19</sup>

#### VITAMIN C DEFICIENCY

Of vitamin C deficiency, only the specific pathologic lesions will be considered. The pathology of scurvy is well known and covered in the books by Aschoff and Koch,<sup>20</sup> Hess<sup>21</sup> and others.

The requirements of all animals for vitamin C are not known. Scurvy, duplicating that in man, can regularly be produced in guinea-pigs and monkeys. The cow, rat, mouse, prairie dog, pigeon and domestic fowl do not require vitamin C in the diet; nevertheless it is found in their livers—evidence that these creatures can synthesize this vitamin.

The gross and microscopic pathologic changes of human scurvy, as seen in the infant and experimental scurvy in the guinea-pig, are so nearly identical that no reasonable doubt can be entertained with regard to applying to the human being the facts ascertained from the experimental studies.

In 1926 Wolbach and Howe<sup>22</sup> characterized the condition of scorbutus as the inability of the supporting tissues to produce and maintain intercellular substances. The effect is therefore on cells of mesenchymal origin in contrast to the ectodermal and endodermal effects of vitamin A deficiency. These conclusions were reached through histologic studies of human infantile scurvy and through studies of the histologic sequences, in growing guinea-pigs, of progressive scurvy and of the repair following administration of vitamin C in natural forms. Subsequently<sup>23</sup> further verification that vitamin C was the only missing factor in scorbutus

concerned in the inability of tissues to produce intercellular material was obtained through the study of reparative processes following administration of crystalline cevitamic acid, orally and parenterally.

Further experimental proof of the correctness of this pathologic characterization was obtained<sup>24</sup> by a comparison of isolated fibroblasts during the organization of blood clots in the complete deficiency with those during the progress of recovery induced by the administration of vitamin C.

The intercellular substances concerned in vitamin C deficiency are the collagen of all fibrous tissue structures, the matrices of bone, dentin and cartilage, and all nonepithelial cement substance, including that of the vascular endothelium. The reparative proliferative powers of epithelial cells, endothelium, fibroblasts and osteoblasts are not impaired, while there is evidence of increased proliferation of osteoblasts, which in the periosteum and at the sites of endochondral bone formation undergo a striking change in morphology, taking on the appearance of young fibroblasts.

Aschoff and Koch<sup>20</sup> anticipated in part these conclusions from their studies of human material. They explained some features of the pathology of bone as due to failure of osteoblasts to form osteoid tissue and, by inference, the hemorrhage of scurvy as due to a failure of cement substance in blood vessels. Mechanical factors were emphasized as determining the sites of hemorrhages in bone, muscle, skin and alveolar processes of the jaws.

Soft tissue changes in vitamin C deficiency, human, and experimental in guinea-pigs, are hemorrhages in regions determined by mechanical stresses and trauma; also anasarca (human) and degenerations of skeletal and cardiac muscle. Hypertrophy of the heart occurs particularly in infants and children, attributed by Erdheim<sup>25</sup> to difficulties in respiration in consequence of the lesions of the ribs at the costochondral junctions. No such explanation can be applied to the cardiac hypertrophy of beriberi or B<sub>1</sub> deficiency. In long continued partial vitamin C deficiency in guinea-pigs, degeneration of skeletal muscle fibers becomes widespread. Affected fibers become completely necrotic. We have found this lesion common also in vitamin A and vitamin G (B<sub>6</sub> + lactoflavin) deficiency.

Goettsch and Pappenheimer<sup>26</sup> describe a diet with adequate vitamin content which leads to a progressive fatal degeneration of the voluntary muscles. The lesion of the individual fibers is identical with that of vitamin deficiencies A, G and C. Furthermore, it was shown by Pappenheimer and his associates<sup>27</sup> that the muscle degeneration was not associated with demonstrable changes in peripheral nerves or their motor terminals. Accordingly, the striking degeneration of muscles in long continued partial experimental scurvy<sup>28</sup> as in acute scurvy must be regarded as secondary effects of vitamin C deficiency. Anemia is another secondary effect of importance. In long continued partial vitamin C deficiency in guinea-pigs, large regions of bone marrow

become devoid of blood forming cells and the seat of a deposit of homogeneous amyloid-like material.<sup>28</sup>

The important gross features of scurvy at all ages are hemorrhages and changes in the bones. The most striking lesions are the subperiosteal hemorrhages and those in the epidiaphyseal junctions of growing bones. All the pathologic features of scurvy are understandable only on the basis of the characterization as a condition of cessation of formation and maintenance of intercellular substances. Calcium metabolism is not primarily affected. In the first period of scurvy, existing cartilage trabeculae at epidiaphyseal junctions become more densely calcified than normally.<sup>29</sup>

In advanced scurvy, calcium salts are liberated through the resorption of bone matrix, which is the process of the osteoporosis of scurvy.

In general, the pathologic picture of scurvy is produced by the resorption of intercellular materials and by the absence of formation of intercellular materials in growth and reparative reactions. Hemorrhages are due to mechanical weakness, occasioned by the lack of collagenous material in fibrous tissue structures and in bone. Diminished cohesion of endothelial cells contributes to the ease with which moderate stresses occasion bleeding in skin and muscles. In the hemorrhages from the gums, the resorption of alveolar processes and the loosening of teeth, the two factors of stresses and loss of intercellular materials are apparent, the first affecting the second.

At the epidiaphyseal junctions in growing bones, the first demonstrable change in experimental scurvy is an increase in the number of osteoblasts applied to the cartilage columns. Formation of cartilage and bone matrices ceases, and the osteoblasts become elongated, assume the shapes of fibroblasts and migrate toward the diaphysis. Here these cells become surrounded by liquid, presumably a deficient product of continued activity toward matrix formation, and give rise to an apparent region of edematous connective tissue at the ends of the diaphysis, the gerüst mark (framework marrow) of German authors.

Marked changes in the epiphyseal cartilage occur because of resorption of matrix. Union between epiphysis and diaphysis becomes severed because the trabeculae of the spongy bone no longer communicate with epiphyseal cartilage, owing to the cessation of formation of periosteal bone. This disunion permits movement of the epiphysis in relation to the diaphysis, and traumatic fragmentation occurs, producing the trümmerfeld zone or zone of disorganization between gerüst mark and epidiaphyseal line. Hemorrhage complicates the picture. This accounts for the complete separation and dislocation of epiphyses so often seen in scorbutic infants and rarely at costocondral junctions in adults. Proliferation of cells, osteoblasts, of the periosteum in contact with the cortical bone is continued in growing bone and is a conspicuous histologic feature of scurvy in infants. A layer of cells without intercellular material thus results and separates periosteum from bone; hence the massive subperiosteal hemorrhages so characteristic of scurvy in infants. These sequences have been worked out in guinea-pigs, yet each stage has been seen in human material.

In growing teeth (incisors) of guinea-pigs, formation of dentin ceases and the pulp becomes separated

from the dentin by liquid, which may be interpreted as due to the continued production by the odontoblasts of a liquid product. Presumably, teeth in process of formation in infants may be similarly affected in scurvy, but direct demonstration is lacking.

*Repair of Scurvy.*—Histologic repair following administration of vitamin C in natural foods or as ascorbic acid is dramatic in character and promptness, and in the small amounts of the remedy required. Newly formed dentin, collagen and bone matrix can be seen after twenty-four hours. Osteoblasts, disguised in morphology as fibroblasts, resume their rôle in formation of bone matrix. New capillary formation becomes possible, so that repair by granulation tissue formation proceeds in organization of blood clots and subsequent callous formation where the hemorrhages were in contact with bone. All normal processes of repair are resumed, infarctions and fractures heal and subperiosteal hemorrhages become in part organized and ossified. In guinea-pigs, dentin formation is resumed in volume and rapidly suggestive of the jelling of a liquid material between pulp and old dentin.

#### VITAMIN D DEFICIENCY OR RICKETS

The physiologic rôle of vitamin D, whether or not identical with the pure substance calciferol or viosterol, in the metabolic processes concerned in the deposition of calcium phosphate in bone is not clear, particularly in relation to the experimental production and cure of rickets in white rats. In the absence of vitamin D, proper amounts and ratios of calcium and phosphate in the diet prevents rickets, yet vitamin D cures rickets produced in the rat by dietary methods. Likewise, restoration of a proper calcium and phosphate intake is curative.

Experimental rickets can be produced also in swine,<sup>30</sup> rabbits,<sup>31</sup> the monkey<sup>32</sup> and the domestic fowl.<sup>33</sup>

Important landmarks in the progress of knowledge of the pathology of rickets are the publications of Pommer,<sup>34</sup> Schmorl,<sup>35</sup> Erdheim<sup>36</sup> and Pappenheimer.<sup>37</sup> An adequate bibliography is contained in Hess's<sup>38</sup> book.

In white rats, experimental rickets, in all phenomena amenable to study, duplicates human rickets. This applies with particular force to the histologic sequences in the development of the lesions and in the repair.

The pathologic conditions of rickets arise from retardation and suppression of sequences primarily concerning cartilage in the endochondral formation of bone and from failure of bone matrix or osteoid to calcify in all locations.

Briefly stated, the sequences disturbed in endochondral bone formation in rickets are as follows:<sup>39</sup> The epiphyseal cartilage during normal growth exists as a narrow plate, supported by bone on the epiphyseal side

and uniformly penetrated by blood vessels of capillary dimensions on the diaphyseal side. Very little evidence of growth is present on the epiphyseal side, where bone is closely applied in the form of transverse trabeculae or a thin fenestrated plate. Growth is accomplished by continuous proliferation of cartilage cells, arranged in columns, on the epiphyseal side, and simultaneous degeneration of the matured cells on the diaphyseal side. The cavities occasioned by the degeneration and disappearance of the cartilage cells at the diaphyseal end of the columns are entered by capillaries accompanied by cells (osteoblasts) which deposit osteoid on the exposed cartilage matrix; hence the first formation of bone is within spaces previously occupied by cartilage cells.

This behavior of the epiphyseal cartilage may be regarded as an ingenious device of nature in order to maintain a continuously retreating gap in the continuity of tissues, which is responded to by vascular outgrowth from the diaphyseal side, comparable to repair of any defect of tissues by the process of organization or granulation tissue formation. In normal growth there is, on the diaphyseal side of the narrow epiphyseal cartilage, a continuous layer of clear or empty cartilage cells, one or two cells deep. In normal growth, calcification of the cartilage matrix lateral to the columns of cells (so-called zone of provisional calcification) extends toward the epiphyseal extremity of the bone only as far as the cartilage cells are markedly degenerated. The first histologic evidence of rickets is the absence in whole or in part of the layer of clear (degenerated) cells and the consequent absence of ingrowth of capillaries. The matrix between the non-degenerated cartilage cells does not calcify. Slight degrees of rickets are manifested by a moderate increase in width of the epiphyseal cartilage presenting an irregular border on the diaphyseal side. This irregularity is due to the fact that the cessation of degenerative sequences in the cartilage cells does not take place simultaneously over the diaphyseal border. The width of the epiphyseal cartilage continues to increase because of the continued activity of the proliferative zone and the survival of the cells on the diaphyseal side. After cessation of the degenerative sequences of the cartilage cells and failure of cartilage matrix to calcify, osteoblasts in relation to the blood vessels in the diaphysis adjacent to the cartilage continue to deposit bone matrix or osteoid that does not calcify.

The degree or measure of severity of rickets may be gaged by the volume of the epiphyseal cartilage and amount of osteoid accumulated in the adjacent diaphysis, both expressions of degree and duration of retardation of two normal processes, one the cartilage sequence and the other, calcification of matrices.

In advanced rickets the noncalcified cartilage at the diaphyseal border becomes transversely stratified in places, evidently a mechanical effect of weight bearing. Osteoid material increases in amount with the duration of the deficiency and, being noncalcified, is molded by the stresses of weight and muscular efforts. Finally, there is disappearance of the cancellous bone of the diaphysis, marked resorption of cortical bone and deposition of subperiosteal osteoid. These are the factors that account for the deformities and fractures of bones in rickets.

*Repair of Rickets.*—The first histologic evidence of repair following corrections of the diet, either by amount of calcium and phosphorus or by administration

of vitamin D, is the presence of cleared or degenerated cells on the diaphyseal border of the cartilage. Simultaneously, calcium is deposited in the cartilage matrix lateral to these cells. These effects are demonstrable at the end of twenty-four hours and are accompanied by extensive vascular responses, as shown by ingrowth of capillaries into empty cell spaces within forty-eight hours.

The first osteoid to be calcified in repair is that laid down in the resumption of normal sequences. The osteoid in the diaphysis that has accumulated during the deficiency subsequently becomes calcified and then is largely removed by osteoclasia. Repair proceeds rapidly in rats, even after severe rickets. From five to seven days suffices to restore the appearances of normal growth almost completely, though there is not complete removal of excess bone.

The osteomalacia of adults, when advanced, presents striking deformities of the skeleton and complicated microscopic pictures, all to be explained by loss of calcium salts in bone, secondary resorption of the matrix and new formation by way of reparative response of cells producing osteoid that does not calcify.

#### VITAMIN B COMPLEX

Present knowledge does not permit a rational account of the pathologic consequences of the deficiencies of what in the past has been called vitamin B or B complex. Vitamin B complex consists of a heat labile fraction, designated as B<sub>1</sub>, and recently isolated in pure form, and a heat stable group. Claims by various authors have been made for as many as six different vitamins in the heat stable group, which is called vitamin B<sub>2</sub> or G. It is fairly certain now that this heat stable group contains probably no more than three vitamins: (1) lactoflavin, already isolated in pure form; (2) vitamin B<sub>6</sub>, the absence of which in the diet of rats is responsible for a characteristic dermatitis affecting the extremities, nose, eyes and ears (this dermatitis has also been referred to as rat pellagra and B<sub>6</sub> as the antirrat pellagra vitamin); (3) the pellagra preventing factor, which also prevents and cures black tongue in dogs.

It is not known whether pellagra and black tongue are due to the same deficiency, although the evidence is very strong that this is the case.

In the human being beriberi is a disease resulting from lack of vitamin B<sub>1</sub>, but in all probability some of the features of this disease as commonly seen are due to other deficiencies. Those pathologic features which may be reproduced in pigeons by means of a diet adequate in all respects except in vitamin B<sub>1</sub> which are common also to human beriberi are some degree of enlargement of the heart, edema, atrophy of muscles, and degenerations of the nervous system. Manifestations of disorder of the nervous system are so striking that the condition in experimental animals is usually called polyneuritis. The conspicuous lesion is degeneration (Marchi degeneration) of the myelin sheaths of peripheral nerves; less certain are degenerative changes in ganglion cells of the brain, cerebellum, spinal cord and dorsal root ganglia. It must be remembered, however, that nervous symptoms appear late in the deficiency, and rats kept on vitamin B<sub>1</sub> deficiency may die without developing nervous lesions, so that a number of workers have questioned the specificity of degenerations of the myelin sheaths and have claimed to have produced the same degree of degeneration in

animals on a starvation diet in the presence of abundant vitamin B<sub>1</sub>.<sup>40</sup> The consequences of starvation on the maintenance of myelin must be determined before the myelin sheath degenerations of this deficiency and other vitamin deficiencies (vitamin A and the heat stable fractions of B) can be attributed to a primary effect on the nervous system. Also of great importance in this connection is the fact that recovery from the nervous manifestations of experimental beriberi takes place in a very short time, and physiologic recovery results in a period of five or six hours following the administration of vitamin B<sub>1</sub>.

I<sup>41</sup> could find no differences in the nerve lesions present in pigeons allowed to succumb with polyneuritis and those in which functional recovery had been induced by treatment. On the whole, it seems best to regard the primary pathologic effects of vitamin B<sub>1</sub> deficiency as not demonstrable at present and to regard all the pathologic changes thus far recorded, including the myelin sheath lesions, as secondary effects. The profound functional disturbances of the nervous system and speedy recovery, with treatment, do indicate that vitamin B<sub>1</sub> is directly concerned in the physiology of neurons. Also among the secondary consequences presumably due to disturbance in carbohydrate metabolism is enlargement of the islands of Langerhans in the pancreas, which I saw in experiments in 1925 and which have been reported by Ogata<sup>42</sup> and by Bierry and Kollmann.<sup>43</sup>

Similar difficulties are encountered in the consideration of the pathology of those conditions and diseases presumably resulting solely from deprivation of heat stable components of vitamin B. There is, for consideration, pellagra in the human being, black tongue in dogs, and rat pellagra or rat dermatitis or, as it is probably now preferably called, as suggested by Birch, György and Harris,<sup>44</sup> "rat acrodynia."

In pellagra, lesions of the nervous system are found but they are not pathognomonic in character. They are degenerative in type, in nerve cells and in myelin sheaths. In pellagra of long standing, lateral and posterior column degenerations in the spinal cord occur. Whether or not such extensive cord lesions have a pathogenesis (atrophy of the gastric mucosa) in common with those occurring in pernicious anemia remains to be solved. In dogs maintained on a diet deficient in the heat stable vitamin B complex (vitamin B<sub>2</sub> or G) extensive degeneration of the myelin sheaths also develop in peripheral nerves and tracts of the spinal cord.<sup>45</sup> Howe, Bessey and I<sup>28</sup> have been unable to obtain degeneration of the myelin sheaths in spinal cord or peripheral nerves in white rats maintained on a similarly deficient diet, even though they were carried to the point of death in the complete deficiency and for very long periods in partial deficiency. It must be concluded that the rat responds differently. The rats in our experiments did develop, as was to be expected,

the skin lesions, or "rat acrodynia." That the factor preventing dermatitis in rats is different from that preventing the lesions of pellagra and black tongue has been proved.<sup>44</sup> It has been shown that diets producing pellagra in man and black tongue in dogs will cure the vitamin B<sub>2</sub> complex deficiency dermatitis of rats. Also, the dermatitis of rats is not influenced by light. We have found it to progress just as rapidly in rats kept in absolute darkness as in those kept in strong light. The distribution is also different and yet we are confronted with the paradox that histologically the lesions of the skin are very similar to those of pellagra and to the lesions of mucous membranes in black tongue of dogs. It is not advisable to describe in detail the histology of the skin lesions of rat dermatitis and of human pellagra. Careful study of rats made during the progress of the deficiency and in repair has failed to throw light on the initial effect in the skin, whether in the epidermis or in the underlying supporting tissues.

Until experiments on animals can be conducted with diets deficient only in single B factors, it would seem not worth while to attempt to characterize, pathologically, these deficiencies.

Until it is proved that the myelin sheath degenerations of the deficiencies are not simply starvation effects, the conclusion is warranted that the demonstrable nervous lesions of all the deficiency diseases are secondary effects and that no one vitamin is concerned in the maintenance of myelin. Lesions of skin and mucous membrane, such as have been described for pellagra, black tongue and rat dermatitis, are not common to deficiencies other than those found in the heat stable fraction of vitamin B or the vitamin B<sub>2</sub> complex, but it does not seem probable that the chemical mechanisms disturbed by the absence of the respective vitamins concerned will be found to occur primarily in the skin and mucous membranes. It may be said that the pathologic histology of pellagra, black tongue and vitamin B<sub>2</sub> or G deficiency in the rat, although presenting many interesting and suggestive features, is at present not more illuminating in regard to the mechanisms involved than are the sequences observed with the naked eye.

#### COMMENT

Our knowledge of the morphologic consequences of vitamin deficiencies is limited and has not extended beyond obvious tissue and cytologic changes.

The pathology of vitamin A deficiency indicates that the seat of the physiologic disturbances is in the epithelial cells. Chemical rôles are suppressed but proliferative powers are not inhibited; neither are the potentialities of cells lost, as is shown by the return to normal physiologic function when vitamin A is restored to the animal.

Vitamin C deficiency affects mesenchymal tissues, the most obvious morphologic consequence being the effect on the formation and maintenance of intercellular materials.

Vitamin D deficiency, besides the well known effect on calcium and phosphorus metabolism, suspends the cartilage cell cycle essential to endochondral growth of bone, though not impairing multiplication of the cartilage cells.

Vitamin B<sub>1</sub>, as is indicated by recovery phenomena from the deficiency, must be more directly concerned in the physiology of the nervous system than is any

other vitamin. The sudden return to normal function after administration of vitamin B<sub>1</sub>, before morphologic repair has been initiated, warrants this conclusion.

A reasonable working hypothesis is that each vitamin is necessary in certain cells for one type of chemical mechanism the suppression of which is compatible.

## NEW FORMS AND SOURCES OF VITAMIN D

CHARLES E. BILLS, Ph.D.  
EVANSVILLE, IND.

Certain facts about vitamin D are widely known. It occurs only rarely in foodstuffs. It is formed in the skin by exposure to ultraviolet rays from the sun or from artificial sources. It is developed in some foodstuffs by their being briefly irradiated. It is produced by irradiating ergosterol, the sterol of fungi. From irradiated ergosterol it can be isolated and crystallized.

The fact that vitamin D is not a single chemical substance has only recently been recognized. The erroneous view still commonly held is that ergosterol is the parent substance, or provitamin, from which all vitamin D arises. Ergosterol exhibits four spectral absorption bands in the ultraviolet region. These bands were observed in the unsaponifiable fraction of the various materials that become antiricketic on irradiation. Since it is rare that even one band, not to mention such a series of bands, is exactly duplicated by different chemical substances, the evidence was misleadingly good that ergosterol was the one and only provitamin D.

I have reviewed elsewhere<sup>1</sup> in considerable detail the history of our knowledge of vitamin D, giving special attention to the experimental work on which its multiple nature is established. In a brief space, this can be recapitulated only in outline and brought up to date. So rapidly has investigation progressed that several new forms of vitamin D have been discovered within the past few months. One of these I shall describe for the first time.

The most thoroughly investigated form of vitamin D is that which results from the irradiation of ergosterol. This is known to physicians under trade names such as viosterol. The chemical name of the pure substance is calciferol. This particular form of vitamin D is also the form that is produced by irradiating yeast, the provitamin of which is ergosterol. It is thus the form that is present in the milk of cows to which irradiated yeast has been administered—the so-called yeast milk of commerce.

In our laboratory, in 1930, Massengale and Nussmeier<sup>2</sup> made the important discovery that the vitamin D of irradiated ergosterol and the vitamin D of cod liver oil act differently on rats and chickens. They found that, rat unit for rat unit, irradiated ergosterol is far less effective than cod liver oil for preventing rickets in chickens. Or, in other words, irradiated ergosterol is far more effective than cod liver oil, chick unit for chick unit, in preventing or curing rickets in rats.

From the Research Laboratory, Mead Johnson & Co.

Read before the Section on Pathology and Physiology at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 14, 1936.

This discovery, like several others in the field of vitamin D, was made simultaneously in more than one laboratory. Mussehl and Ackerson<sup>3</sup> and Hess and Supplee<sup>4</sup> came to the same conclusions from slightly different avenues of approach. It is recalled that Hess<sup>5</sup> and Steenbock<sup>6</sup> announced the discovery of activation within a few weeks of each other, that the provitamin concept was promulgated by three groups of investigators<sup>7</sup> Dec. 10, 1926, and that the high relative efficacy of irradiated 7-dehydro-cholesterol for chickens was reported by two independent groups<sup>8</sup> on the same day a few weeks ago.

The device of employing two species of test animals for assay purposes has come to be an extraordinarily useful tool in studies on the multiple nature of vitamin D. The knowledge that one species responds better to one form of this vitamin while another species responds better to another form has prompted investigators to compare the effectiveness of cod liver oil and irradiated ergosterol, rat unit for rat unit, on human beings. Differences have been claimed and denied. There is agreement to the extent that the difference, if any, is not large. Most of this work has been of poor quality, with groups of children so few in number and so diverse in age and background that the recorded observations are unimpressive to one who is familiar with the proper use and grouping of animals for the conduct of a biologic assay. Birds other than the common fowl, for example turkeys, respond like the common fowl, and mammals other than the rat, e. g., man, respond at least somewhat like the rat to these two kinds of vitamin D. It is therefore reasonable to expect that, if the number of species put to the test is extended, mammals in general will be found to respond well (per rat unit) to either irradiated ergosterol or cod liver oil, and birds in general will do poorly with irradiated ergosterol but will do well with cod liver oil.

The chemical constitution of the sterols is fairly well understood. The conventional numbering of the sterol ring, and the probable formulas of cholesterol, ergosterol and calciferol are shown in the accompanying structural formulas. From these concepts, the organic chemist has built several new vitamins D.

Windaus and Langer<sup>9</sup> added two atoms of hydrogen to the side chain of ergosterol at position 22. The new compound, 22-dihydro-ergosterol, gave by irradiation a new vitamin D, presumably 22-dihydro-calciferol. McDonald<sup>10</sup> has recently found that this slight molecular alteration increases by several times the effectiveness of the vitamin, per rat unit, for chickens.

Two years ago Waddell<sup>11</sup> made the surprising discovery that, in chicken-and-rat comparisons, irradiated cholesterol resembles cod liver oil and differs greatly from irradiated ergosterol, unit for unit. It occurred to Callow<sup>12</sup> and to me<sup>13</sup> that by removing the methyl group at position 24 in the ergosterol side chain, in addition to introducing the hydrogen at position 22, a new provitamin D might be obtained which, on theoretical grounds, should give rise to a vitamin D simulating that of cod liver oil or, more particularly, of irradiated cholesterol. Such a provitamin would be a demethyldihydro-ergosterol, or, in terms of cholesterol, 7-dehydro-cholesterol. Windaus, Lettré and

Fig. 2.—Cholesterol.

Fig. 3.—Ergosterol.

Fig. 4.—Calciferol, a form of vitamin D (a recent tentative formula).

Schenck<sup>13</sup> have synthesized this compound and found that, when irradiated, it gives a product effective in rat rickets. Repeating the synthesis, McDonald and I have confirmed the observations of the German workers and have substantiated the predictions by the discovery that, rat unit for rat unit, irradiated 7-dehydro-cholesterol is more effective than irradiated 22-dihydro-ergosterol and much more effective than irradiated ergosterol for chickens.<sup>14</sup> The Kochs<sup>15</sup> report similar results.

It was known that the activatability of cholesterol depended for the most part on its minute content of a provitamin, which had the same spectral absorption bands as ergosterol and which every one presumed to be ergosterol. These bands are also exhibited by 7-dehydro-cholesterol, and this fact, together with the behavior of the corresponding vitamin with chickens, suggests that 7-dehydro-cholesterol is the provitamin D in ordinary cholesterol. Many assays must still be carried out to establish whether 7-dehydro-cholesterol and the natural cholesterol provitamin, which are certainly similar, are actually identical. If they are identical, it probably follows that irradiated milk, which is activated by virtue of its cholesterol provitamin content, contains irradiated 7-dehydro-cholesterol and that this form of vitamin D, far from being a laboratory curiosity, is already an important practical source.

Another form of vitamin D was announced by McDonald<sup>10</sup> in March. This is irradiated 7-hydroxy-cholesterol or an impurity associated therewith. The absorption spectrum of 7-hydroxy-cholesterol is entirely different from that of the other provitamins D that I have mentioned. It consists of one rather wide band in place of the usual four, and general absorption in the far ultraviolet. In this connection, one recalls that cholesterol, specially treated to remove its ordinary provitamin, develops a new provitamin when heated.<sup>14</sup> The spectral absorption is general, no "ergosterol" bands being evident. It is thus possible that the provitamin developed by heating (with incidental oxidation) is 7-hydroxy-cholesterol or some similar substance.

It has been shown that the usual procedure (bromination, debromination) by which the ordinary provitamin is removed from crude cholesterol never completely destroys the activatability of the cholesterol.<sup>15</sup> Little is known of the residual provitamin, but Hathaway and Lobb<sup>14</sup> have recently reported that the vitamin D which results from irradiating it is much less effective, rat unit for rat unit on chickens, than the vitamin D produced by irradiating cholesterol which had first been purified and then heated to develop the new provitamin. In other words, this obscure form of vitamin D acts like calciferol, but since it is chemically impossible for it to be calciferol it must be recognized as still another kind of vitamin D.

The new vitamin D that McDonald and I announce at this time is prepared by irradiating a provitamin derived from sitosterol, the sterol of the higher plants which corresponds to cholesterol of animals. The provitamin is prepared by oxidizing sitosterol, reducing the oxidation product, treating the reduced material with benzoyl chloride in pyridine, and heating and saponifying the resulting ester. The procedure is similar to that used in preparing 7-dehydro-cholesterol. The provitamin exhibits a series of absorption bands and becomes antiricketic on exposure to ultraviolet rays.

Finally, I come to two forms of vitamin D that are produced by means other than irradiation. They have been known for some years, but only as curiosities. One of them supplied the first evidence of the multiple

nature of this vitamin. In 1926 McDonald and I<sup>16</sup> obtained a crude antiricketic product by treating cholesterol with a clay catalyst. We observed that this vitamin D, unlike the vitamin D of cod liver oil or irradiated cholesterol, was resistant to destruction by butyl nitrite. Yoder,<sup>17</sup> in reconsidering our reaction, suspected that the active principle involved was a derivative of the hydrocarbon cholesterolene. He found that cholesterolene sulfonic acid is a vitamin D, not very active to be sure, but extremely interesting to the chemist.

The other curiosity was described by us<sup>18</sup> in 1931. We found that ergosterol, when treated with nitrites, yielded an antiricketic derivative. Little is known of its chemistry, except that it differs from Yoder's product and also from any form of the vitamin that is not resistant to nitrites. Neither of these two forms of vitamin D has come into practical use, and we are reasonably certain that neither occurs in fish oils.

Thus we distinguish eight forms of vitamin D, and it seems probable that others can be produced. In fact, the number of possible forms may well be as many as the number of sex hormones which, as sterol derivatives, are chemically related to the vitamins D. The study of the effect of slight differences in molecular configuration on vitamin action has only just begun.

During the past ten years we have assayed the liver oils of about 130 species of fish, including nearly all which are of major importance commercially. A number of these were less potent than cod liver oil, but the majority were more potent. The oils of certain species, particularly the big percomorphs, exhibited from 100 to 1,000 times as much vitamin D per gram as cod liver oil, when assayed with rats. It occurred to us, in view of the numerous vitamins D prepared *in vitro*, that the vitamin D of these vastly different fish oils might vary in kind as well as in concentration.

We assayed the liver oils of twenty-five species of fish with both rats and chicks, finding, indeed, that the different oils varied greatly, rat unit for rat unit, in their effectiveness on chicks.<sup>8a</sup> The largest difference was observed between the oil of white sea-bass, *Cynoscion nobilis*, and certain species of tuna. The former was about twenty times as effective for chicks, per rat unit, as the latter.

Since it is inconceivable that each species of fish has its own private form of vitamin D, it must be concluded that any given fish oil probably contains at least two vitamins D, the proportions of which vary with the species. In other words, the vitamin D of fish oils can no longer be regarded as a single substance. It remains to be demonstrated which, if any, of the known forms of vitamin D occur in fish oils and whether any particular form is therapeutically more desirable than any other.

#### SUMMARY

Eight forms of vitamin D have been artificially prepared. At least two forms occur in fish oils, which may or may not be identical with certain of those made *in vitro*.

## THE PRESENT STATUS OF VITAMIN DEFICIENCIES IN PRACTICE

JOHN B. YOUMANS, M.D.

NASHVILLE, TENN.

It is becoming better and better recognized that the mild or latent forms of the vitamin deficiencies are more important in practice at present than the fully developed cases. The latter are uncommon, are easily recognized and are usually promptly and adequately treated. On the other hand there is reason to believe that minimal or mild forms of these diseases are much more frequent, often escape recognition and, because of their insidious effect on large numbers of people, constitute a more serious problem than the occasional advanced cases. It is true that the diagnosis of these mild forms is often difficult and uncertain. Nevertheless, there is available today much new knowledge of the vitamins which is applicable to the diagnosis and study of the milder forms of their deficiencies in patients. It is my purpose in this paper to describe the present means of diagnosis of the mild or early forms of each of the avitaminoses and to discuss briefly their incidence and certain aspects of treatment. No attempt will be made to present all the signs, symptoms or diagnostic procedures, even though they are present in the early and mild forms, my purpose being to select those which are most suitable, reliable and specific. Neither will it be possible to give a complete description of methods and technic in all cases. Because of the limitations of my experience, my remarks will deal principally with these disorders as they occur in adults.

A general statement regarding the incidence of these diseases should be made. In any given practice it will vary with the geographic location and with the economic status, age, sex and occupation of the patients. These, however, are factors that are of greatest importance in the primary or idiopathic forms of these diseases. Because of the probably high incidence of mild avitaminoses as complications of other disease, they must be of vital interest to all physicians irrespective of the nature of their practices.

#### VITAMIN A

Avitaminosis A is generally considered to be rare in this country, particularly among adults. For example, only four or five cases of xerophthalmia in adults have been reported in this country,<sup>1</sup> and in a recent questionnaire the number of cases of outspoken night blindness reported by a group of ophthalmologists was very small.<sup>2</sup> However, these are manifestations of severe A deficiency and do not measure at all adequately the incidence of the milder forms of this disease. Using newer methods of diagnosis, Jeans and Zentmire<sup>3</sup> recently reported forty-five cases of probable mild deficiency among a group of 213 children. In a more recent paper<sup>4</sup> the same authors found from 26 to 75

per cent of children of different social groups with evidence of A insufficiency. Park<sup>5</sup> examined a large number of subjects, both adults and children, some supposedly normal and others suffering from different diseases, and found evidence of a mild deficiency in a considerable number. The work of Frandsen,<sup>6</sup> although

Fig. 1.—Smear from the bulbar conjunctiva of a white housewife, aged 52, who complained of vague pains in the arms, poor vision, pain and burning in the eyes and slight photophobia. There is marked cornification of all the cells.

done in Denmark, suggests that even in this country many more cases of mild vitamin A deficiency exist, both in children and in adults, than are recognized at present.

The earliest and the most reliable evidence of slight vitamin A deficiency is mild hemeralopia or a slightly lowered dark adaptation. The recent work of Jeans and Zentmire<sup>7</sup> and of Frandsen<sup>6</sup> seems to have demonstrated conclusively that clinically this symptom is most often a result of vitamin A deficiency and that it is often present long before other manifestations of the disease present themselves. In its earliest stages it may exist without the patient's knowledge or the patient may recall or recognize the symptom only after questioning. The abnormality may be detected by the use of the Birch-Hirschfeld photometer<sup>8</sup> or by the more simple apparatus described by Edmund and Ulrich Möller<sup>9</sup> and used by Helga Frandsen<sup>6</sup> in her study.

A second test consists of making a smear from light scrapings of the bulbar conjunctiva.<sup>10</sup> When properly stained, the presence of cornified epithelium indicates a deficiency of vitamin A (figs. 1 and 2). Sweet and K'ang<sup>11</sup> believe that this offers one of the most reliable methods of early diagnosis, though it is probable that in many cases hemeralopia precedes the changes in the conjunctiva. Nasal scrapings also may show a cornification of the epithelium. Asthenopia, poor vision, photophobia, Bitot's spots, conjunctival complaints and

a dryness and granular appearance of the bulbar conjunctivae when the lids are held open for a few minutes occur as early manifestations of A deficiency and, while not specific, should arouse suspicion and lead to further tests.

The specific lesions in the skin have been only recently described<sup>12</sup> and are not widely known. They consist of keratotic papules of varying size, distributed especially over the thighs, arms and shoulders, surrounding and arising from the pilosebaceous follicles. Microscopically the ducts are distended and the openings are plugged with masses of cornified epithelium. There is atrophy of the glands and hyperplasia of the epidermis. The eruption is more common in adults and is said to be rare in children, which is of some diagnostic importance. In a fully developed form the eruption probably represents a late or severe deficiency. However, less extensive eruptions may occur in the milder forms, and I have observed two patients with papular lesions of this nature which disappeared after treatment with cod liver oil (figs. 3, 4, 5 and 6). Recently Scheer and Keil<sup>13</sup> have reported that the papules of vitamin C deficiency in the earlier or milder cases may resemble very closely those of vitamin A lack and have suggested the combined use of the capillary resistance test and biopsy in diagnosis. In all cases of vitamin A deficiency, confirmation of the diagnosis may be obtained by the result of adequate treatment with vitamin A, the changes in the eye particularly responding promptly to this measure.

#### VITAMIN B<sub>1</sub>

The frequency of mild vitamin B<sub>1</sub> deficiency in this country is hard to estimate, though an endemic form

Fig. 2.—Smear from the same patient as in figure 1 after two weeks' treatment with cod liver oil. Many of the cells now are nucleated and show a return toward normal.

exists in Louisiana<sup>14</sup> and sporadic cases of beriberi or beriberi-like diseases are occasionally reported. Recent studies indicating that so-called alcoholic neuritis,<sup>15</sup> the

polyneuritis of pregnancy,<sup>16</sup> and other forms of peripheral neuritis<sup>17</sup> are in fact B<sub>1</sub> deficiency neuritis add additional groups of disorders to those caused by lack of this vitamin. Vorhaus, Williams and Waterman<sup>17</sup> have recently offered a clinical classification of B<sub>1</sub> deficiencies which includes a group with less specific

Fig. 3.—Papular lesions on the thigh of a Negress, aged 46, who complained of bronchitis, "pains all over," swelling of the feet, nervousness, weakness and anorexia.

symptoms such as anorexia, vague pains, weakness, indigestion and hypotonicity of the bowel (x-ray). If, as seems probable, such conditions are to be included, mild cases of the disease are common.

No conclusive symptom, sign or diagnostic test of minimal vitamin B<sub>1</sub> deficiency exists so far as I am aware. However, two procedures have recently become available which, together with symptoms suggestive of the disease, are helpful in diagnosis. The first is a calculation of the adequacy of the vitamin B<sub>1</sub> intake according to Cowgill's formula.<sup>18</sup> Jolliffe, Colbert and Joffe<sup>15</sup> have recently applied Cowgill's formula with great success in cases of so-called alcoholic neuritis. The second is the therapeutic test of giving the purified vitamin. The latter is, or will shortly be, available in a form suitable for parenteral administration. Unfortunately the signs and symptoms that would be expected to respond to this treatment are not specific and many of them are said to be caused by other vitamin deficiencies. Therefore, the absence of complete relief by adequate treatment does not preclude the presence of some avitaminosis B<sub>1</sub>.

#### VITAMIN B<sub>2</sub> (G)

The evidence with respect to the frequency of mild B<sub>2</sub> deficiency is much more convincing than in the case of B<sub>1</sub>. Assuming that pellagra is due to a deficiency of this factor, the condition is endemic in many parts of the South, and mild or early cases are common. More and more sporadic cases of pellagra are reported from other regions<sup>19</sup> and the existence of many mild or incomplete forms of the disease seems very probable.

Except for the dermatitis, the available means for the diagnosis of mild vitamin B<sub>2</sub> deficiency (pellagra) are

no more satisfactory than in the case of B<sub>1</sub> deficiency. To the pellagra-conscious physician the presence of even slight changes in the skin consistent with the early dermal lesions of pellagra are sufficient to arouse a suspicion of the disease, as are the less specific symptoms of glossitis, diarrhea, digestive disturbances, and nervous and mental disorders. In addition to these symptoms there remains only a study of the diet and the therapeutic test, which in mild cases may be done by giving autoclaved yeast or, better still, the more potent liver extract, which may be given parenterally to avoid difficulties in absorption. Knowledge of the possible effects of deficiency of the other components of the B complex is still too incomplete to warrant a discussion of their clinical aspects.

#### VITAMIN C

Frank scurvy in adults is undoubtedly not common in most countries, though sporadic cases are occasionally reported, and it is found somewhat more frequently in children. In contrast, mild or latent scurvy or, better, a slight deficiency of vitamin C is probably very common. Harris and Ray,<sup>20</sup> using the newer clinical tests, found a number of children and adults who gave evidence of this condition, and many individual cases have been reported by others. My associates and I<sup>21</sup> found evidence of a mild insufficiency of vitamin C in twelve of fifteen adults whose diets were suspected of being inadequate in this factor. More significantly, of

Fig. 4.—Section of skin from the same patient as in figure 3, showing the hair follicle filled with a mass of keratinized debris.

a group of sixteen presumably normal subjects selected for controls eight were found to have evidence of this deficiency.

The recent isolation, identification and synthesis of vitamin C<sup>22</sup> (cevitamic acid) have made it possible to

study the excretion of this vitamin and its content in the tissues and body fluids. Although a final decision regarding normal values must wait until optimum requirements under various conditions have been determined, three possible methods for determining an inadequate intake, or store of vitamin C in the body, are available. These are (1) determinations of the daily excretion (urine), (2) a test of the body store ("saturation" or "retention" test) and (3) a determination of the amount of vitamin present in the blood plasma or serum.

Fig. 5.—Papular lesions in a diabetic girl, aged 20.

ration" or "retention" test) and (3) a determination of the amount of vitamin present in the blood plasma or serum.

The amount of vitamin C in the urine is determined by a simple titration method using various indicators, the most useful clinically being dichlorophenolindophenol.<sup>20</sup> Because single specimens vary greatly in their content, the twenty-four hour excretion must be measured. Specimens may be examined singly during the twenty-four hours or the twenty-four hour specimen, suitably preserved, may be used. The method is sufficiently simple for office use and is, in fact, less trouble than the quantitative estimation of dextrose in the urine. As a result of our studies we<sup>21</sup> have tentatively adopted an excretion of 20 mg. a day as the lower limit of normal excretion under usual circumstances. It should be emphasized that this does not necessarily represent an optimum state under any or all conditions.

The "saturation" or "retention" test<sup>20</sup> is performed by giving a large amount of vitamin C (600 mg. in adult) either as pure cevitamic acid or as orange juice, and determining the excretion in the urine in the twenty-four hour period during which the test dose is administered. In patients with a poor store of vitamin C the greater part of the test dose is retained (little is excreted), while in those with a good store a large part is eliminated. While final standards have

not been set, my associates and I have taken the excretion of at least 30 per cent of such a test dose as the lower limit of normal under ordinary conditions in an adult<sup>21</sup> (fig. 7).

Finally, the amount of vitamin C in the blood plasma or serum may be determined. Normal values have not been finally established and will vary, depending on whether total or reduced cevitamic acid is determined according to the method used.<sup>23</sup> Farmer and Abt<sup>23</sup> found from 1.030 to 2.29 mg. per hundred cubic centimeters of reduced cevitamic acid in adults, and from 0.819 to 1.374 mg. in children whose diets were believed to be satisfactory. The same authors found 0.687 and 0.917 mg. in two adults and 0.458 and 0.617 mg. in two children whose diets may have been deficient. In normal subjects on a usual or forced intake of vitamin C my associates and I, using a similar method, have found values of from 1.66 to 4.31 mg. per hundred cubic centimeters. In twelve patients whose diets were suspected of being low in vitamin C, some of whom showed signs and symptoms compatible with mild vitamin C deficiency, the values ranged from 0.254 mg. to 1.09 mg., with an average of 0.539 mg. However, the intake of even moderate amounts of vitamin C causes a quick, though temporary, rise in the blood. Furthermore, with a low vitamin C intake, for even a short period, the concentration in the blood falls to a relatively low level, though there is a good store

Fig. 6.—Same area as shown in figure 5 after six weeks' treatment with cod liver oil.

in the body and no evidence of a deficiency.<sup>24</sup> Obviously, both these factors must be taken into consideration in interpreting values found on examination of the blood.

23. Mirsky, I. A.; Swadesh, S., and Soskin, Samuel: Total Ascorbic Acid Content of Human Blood, *Proc. Soc. Exper. Biol. & Med.* 32: 1130 (April) 1935. Farmer, C. J., and Abt, A. F.: Ascorbic Acid Content of Blood, *ibid.* 32: 1625 (June) 1935.

24. Youmans, J. B., and associates: Unpublished data, 1936.

Besides these tests there is the test of capillary resistance. This procedure, as modified by Göthlin,<sup>25</sup> consists of counting the number of petechial hemorrhages that appear in an area of skin of 60 mm. diameter in the antecubital fossa, after fifteen minutes of venous stasis with a blood pressure cuff at a pressure of 50 mm. of mercury. The appearance of more than eight is considered positive, of less than five negative. Although not specific, the results of such a test have been found to correspond well to the probable state of vitamin C intake and store and the therapeutic administration of the vitamin.<sup>25</sup> In the absence of other causes for such hemorrhages, a positive test is strong evidence of a vitamin C deficiency.

#### VITAMIN D

Vitamin D deficiency appears to be uncommon in adults and occurs sporadically mainly as a complication in diseases that interfere with the absorption of food.

In children the presence of a deficiency in vitamin D may be readily shown by the presence of characteristic lesions in the long bones, as seen in roentgenograms. In the adult no satisfactory clinical test exists and in any question of vitamin D deficiency there is involved the problem of calcium, phosphorus and parathyroid hormone metabolism as well. Deficiency of vitamin D is to be suspected when the diet appears to be lacking in the vitamin, or in the presence of such conditions as osteoporosis, osteomalacia, tetany and insufficiently explained fractures. It is particularly to be looked for in the presence of conditions that lead to a greater demand for this vitamin, such as pregnancy or lactation, or in diseases that interfere with its absorption and utilization, such as celiac disease, chronic jaundice and external biliary fistula. In suspected cases the effect of adequate treatment with the vitamin may be helpful diagnostically.

#### VITAMIN E

Too little is known of the clinical effects of vitamin E deficiency to warrant an extended discussion of its frequency or diagnosis. The vitamin is held so tenaciously by the tissues, the source is so varied and the supply so abundant that deficiencies are probably rare. There is evidence,<sup>26</sup> however, that some cases of functional sterility and habitual abortion are caused by a lack of this vitamin and in such cases this deficiency is to be suspected.

From this review of the incidence and diagnosis of the avitaminoses it may be concluded that all who are engaged in practice must be conscious of the existence of these disorders and alert to detect them. Because these deficiencies occur not only as independent diseases but perhaps even more often as complications of other diseases, this applies not only to the physician in general practice and the internist but to every specialist as well. Any patient whose intake of food is restricted

from any cause, or in whom there is any interference with its absorption or utilization, or whose need for the vitamins is increased should be examined critically for the possible presence of a vitamin deficiency.

One's suspicions having been aroused, the further steps in study, diagnosis and treatment may be outlined briefly as follows: First, a careful scrutiny of the diet. I would emphasize the necessity for careful and detailed, often minute, inquiry. The importance of the quantitative factor in diets alone makes this necessary. Much too often in the past, physicians have been satisfied with a few cursory questions. I have found it helpful to have the patient record the kind and amount of food eaten over a period of a week or more. While errors are possible with this method, it has proved a valuable aid in diagnosis, and I have frequently been astonished at the dietary deficiencies it has disclosed. It is also useful as a basis for further questioning at a subsequent visit.

The second step is to test by such methods as those just described for the presence of the various vitamin deficiencies. Because of the frequency of multiple deficiencies and the similarity of the symptoms produced by them, particularly in mild deficiency states, it will often be necessary to test for the presence of several deficiencies, though symptoms and a consideration of the diet may indicate that which is probably preponderant.

The third step is treatment with the specific substances. This may also be of considerable diagnostic importance.

In treatment a number of factors may influence the response and hence are important diagnostically and therapeutically.

When the therapeutic test is used, the preparations should be as pure as possible. Because of multiple deficiencies, treatment with several of the vitamins may be necessary and it may be helpful to administer them successively. The factor of dosage is of great importance, particularly in treatment or cure as contrasted with prevention. This is especially true when the avitaminoses complicate other diseases, when there is interference with absorption and utilization, or an increased demand. When absorption by the usual routes is hindered, administration should be by routes that insure absorption. In prophylaxis, in very mild deficiencies or to maintain a cure, considerations of economy and palatability, as well as common sense, indicate the use of natural foodstuffs. In these circumstances, however, it will be necessary to insure availability, proper preparation of food, and the continuance of an adequate intake.

At the present time no pure or injectable preparations of vitamin A are available and for administration the richest preparations are certain fish oils. Carotene, the precursor of vitamin A, may be given, even parenterally, but the evidence of Drummond, Bell and Palmer<sup>27</sup> would suggest that under many conditions

Fig 7.—Daily excretion of vitamin C and result of saturation test in a woman, aged 61, with edema, hypoproteinemia, gingivitis and dermatitis; 600 mg. of vitamin C was given at the point marked by the arrow without any significant increase in the daily excretion.

vitamin A is to be preferred to carotene because the former is better absorbed by mouth.

Vitamin D is available in concentrated form, and large doses may easily be given by mouth or through the skin. Only in the case of this vitamin does there appear to be any danger of inducing a hypervitaminosis. The toxic dose is so large, however, that this danger is encountered only rarely. The symptoms of early hypervitaminosis D have been summarized by Bills.<sup>28</sup>

The need for vitamin B<sub>1</sub> is affected by so many factors that it seems unwise to set any single amount as the minimum requirement, and little is known about the optimal supply. Vorhaus, Williams and Waterman<sup>17</sup> believe that the minimum daily therapeutic dose that can be relied on to abolish any accumulated deficit and supply current needs is 10 mg. of the pure material. Vitamin B<sub>1</sub> will soon be available commercially in pure crystalline form, injectable and hence of value in ensuring adequate intake and certain absorption. However, because other fractions of the vitamin B complex may be concerned in the production of symptoms, it may often be advisable in treatment to employ more complex products, such as the concentrated yeast and wheat germ preparations.

In pellagra, Spies<sup>19</sup> has shown that energetic treatment by diet, symptomatic measures and the administration of large doses of vitamin preparations, including liver extract or ventriculin, orally or parenterally, will greatly reduce the mortality in even desperate cases. The need for intensive treatment varies with the severity of the illness, and mild cases will permit the use of specific substances alone when a therapeutic test is desired. Subsequent control of the diet is important to prevent relapses, especially in cases in which there are difficulties in absorption.

Pure vitamin C (cevitamic acid) is now available at prices that compare favorably with orange juice. Minimum protective doses are usually considered to be in the neighborhood of from 25 to 40 mg. daily, but knowledge of the occurrence of mild deficiencies suggests that this amount should be larger and optimal amounts considerably greater. When necessary, pure vitamin C may be given intravenously if precautions are taken to neutralize it when large doses are given. When vitamin C is administered in the form of fruit juice the vitamin content should be determined, especially in the case of canned juice, some brands of which contain practically no vitamin C.<sup>29</sup> Natural juice also varies in its potency, and caution should be taken to avoid loss by standing.

It is to be feared that the frequency of these disorders, the presence of multiple deficiencies in many cases and the absence of clear cut signs or symptoms in the milder forms will foster careless and incomplete diagnosis and the complacent acceptance of such general terms as "deficiency disease," "multiple avitaminosis" and the like. This attitude will in turn lead to the uncritical use of complex mixtures in treatment.<sup>30</sup> Such a practice is no more justified than failure to diagnose other diseases accurately. One might as consistently make a diagnosis of heart disease and give digitalis, glyceryl trinitrate, diuretics and thyroid extract, without attempting to determine the etiology, pathologic

changes and functional disorders. The only proper procedure in every case of suspected vitamin deficiency is to determine the nature of the deficiency and the pathologic and functional changes resulting from it, as completely as possible. In this way the clinician not only insures accurate, complete diagnosis and proper treatment but is able to contribute to our knowledge of the vitamins as they relate to human health.

#### SUMMARY

Briefly, the minimal forms of vitamin deficiencies are important problems in all forms of practice. Although diagnosis is more difficult in these cases, there are available methods which may be employed successfully in many cases, and every effort should be made to secure an early and accurate diagnosis. For the early diagnosis of vitamin A deficiency there is available a test of slight hemeralopia and the examination of smears from the bulbar conjunctivae. In vitamin B<sub>1</sub> deficiency states the adequacy of the vitamin intake may be calculated as a presumptive test, to be substantiated by the results of treatment with the pure vitamin. In mild vitamin B<sub>2</sub> deficiency, diagnosis depends on suggestive clinical symptoms, a study of the diet and the therapeutic results of relatively pure products such as autoclaved yeast and liver extracts. Slight degrees of vitamin C deficiency may be detected by urinalysis and the response to large test doses of the vitamin. The diagnosis of vitamin D deficiency in adults is difficult because of the complicating factors of calcium, phosphorus and parathyroid metabolism. At the present time vitamin E deficiency may be suspected only by the presence of clinical symptoms and a consideration of the diet. In most cases potent and concentrated preparations of the vitamins are available for critical and scientific treatment of these deficiency states.

#### ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. WOLBACH, BILLS AND YOUNG

DR. ARTHUR F. ABT, Chicago: Dr. Chester J. Farmer and I have recently completed an investigation on the concentration of cevitamic acid (reduced) in the blood plasma in normal and abnormal states. By the use of a microchemical method devised by us, we have determined the reduced cevitamic acid content of the blood plasma in a group of infants and children on adequate vitamin C containing diets. No correlation between the age of the individual and the cevitamic acid content of the blood plasma could be demonstrated. Our results fail to substantiate the synthesis of cevitamic acid in infants. A definite correlation between blood plasma values and capillary skin resistance tests could not be demonstrated. Single determinations of cevitamic acid in the blood plasma are an accurate index for the detection of clinical scurvy. From our experience to date, we feel that the level (in milligrams per hundred cubic centimeters) of reduced cevitamic acid in a single blood sample taken on a fasting stomach is indicative of the tissue saturation. Blood tolerance curves and twenty-four hour urine excretion values bear out this opinion. In other words, if one wishes to investigate tissue saturation to determine whether there is a prevalence of subclinical scurvy or whether a number of children in any region are lacking in dietary vitamin C, single blood determinations will give the desired information. We now have a technic whereby, instead of puncturing a vein, we may take a few drops of blood from the finger or heel, which will yield an accurate value and which we feel is a much simpler method than taking twenty-four hour urine specimens. With the aid of the microchemical method, hourly blood determinations can be plotted. Our results indicate that the occurrence of congenital scurvy is possible. We feel that cevitamic acid blood plasma values are a better index in healing scurvy than tests for capillary skin resistance or serial

x-ray films of the long bones. Blood plasma values show a rapid rise in a healing scurvy, and a single blood determination is more informative than a single or twenty-four hour urinary determination. We conclude that the cevitamic acid (reduced) content of the blood plasma varies directly with the vitamin C content of the diet. If complete metabolism studies on vitamin C are to be made, absorption by the gastro-intestinal tract must be considered and it must also be recognized that there are other channels of excretion than the urine. It is already known that cevitamic acid is present in significant quantities in the saliva and the milk. Elimination through the gastro-intestinal tract must also be considered in diarrheal states, so common in infancy and childhood.

DR. S. B. WOLBACH, Boston: I should have explained what I meant by specific starvation. In vitamin A deficiency, for example, the cell in one sense is not starved; in fact, I think that the proliferative power of the epithelial cell as shown by its regeneration is increased, yet that cell is not able to do something it formerly did, and that is the connotation I wish to give to specific starvation, not cell hunger in the broad sense.

## THE OLFACTORY BULBS IN EXPERIMENTAL POLIOMYELITIS

THEIR PATHOLOGIC CONDITION AS AN INDICATOR  
OF THE PORTAL OF ENTRY OF  
THE VIRUS

ALBERT B. SABIN, M.D.

AND

PETER K. OLITSKY, M.D.

NEW YORK

It has been repeatedly shown by many investigators<sup>1</sup> that when the virus of poliomyelitis is instilled intranasally in rhesus monkeys it enters the central nervous system by way of the olfactory nerves and bulbs. Our purpose in the present communication is to describe the pathologic changes produced by the virus in its passage through the olfactory bulbs and to present evidence that these changes occur only when the virus has reached the bulbs from the periphery by way of the olfactory nerves and not when the invasion of the central nervous system is by other pathways.

Experimental poliomyelitis in rhesus monkeys was produced almost constantly by instilling 1 cc. of a 10 per cent virus suspension (M. V. strain) into each nostril on one day and repeating the process forty-eight hours later. With this procedure the first rise of temperature occurs between the fourth and sixth days and paralysis first appears on the seventh to ninth days after the first instillation of virus. The olfactory bulbs were fixed in Zenker's fluid containing 5 per cent glacial acetic acid, embedded in paraffin, and sections cut at 5 microns were stained with phloxine and methylene blue. As a rule the entire bulb was embedded with the anterior pole downward, and transverse sections were obtained from at least four to six different levels.

The earliest examination was made on the fourth day after the first dose of virus. At this time the lesions were already present and involved several layers of the olfactory bulbs from without inward. The outer layer of olfactory nerve fibers and the adjacent layer of

glomeruli were diffusely infiltrated with inflammatory cells, consisting of polymorphonuclear leukocytes, mononuclear cells and lymphocytes. Polymorphonuclear cells were also scattered through the lamina granulosa externa and the lamina gelatinosa, the layers between the glomeruli and the mitral cells. The large mitral cells, which at the glomeruli are in synaptic relation with the primary olfactory neurons situated in the nasal mucosa, showed advanced necrotic changes, while the smaller cells in the internal granular layer among which they lie appeared to be generally well preserved. Many of the mitral cells were reduced to structureless, acido-

philic masses with pyknotic, shrunken nuclei, and some were undergoing neuronophagia. With these changes in the olfactory bulbs on the fourth day after instillation and approximately four days before the onset of paralysis the spinal cord still appeared normal, while lesions were already present in the diencephalon, mesencephalon and pons. In monkeys examined after the onset of paralysis or post mortem, further changes in the olfactory bulbs consisted of neuronophagia of the involved mitral cells and an increased inflammatory process in the peripheral layers where the blood vessels showed characteristic perivascular cuffing. With the exception of an occasional polymorphonuclear leukocyte, no lesions were seen in the center of the bulb.

beyond the layer of mitral cells. Intranuclear inclusions of the type described in experimental poliomyelitis<sup>2</sup> were not found in the bulbs even when examined on the fourth day, probably because necrosis had already advanced to too late a stage. That the method was suitable for demonstrating them is evident from the fact that they were observed elsewhere in the central nervous system.

Fig. 2.—Transverse section of olfactory bulb four days after nasal instillation of poliomyelitis virus. At this magnification only the diffuse inflammatory reaction in the outer layers is perceptible.  $\times 40$ .

The pathologic changes just described were found in the olfactory bulbs of each of the eighteen monkeys that had been infected by the intranasal route and examined for the most part at the termination of the disease. The type and extent of the lesions varied in individual animals. In some many mitral cells were destroyed, while in others only a few. The intensity of the peripheral inflammatory reaction did not appear to depend on the number of necrotic nerve cells, for it was marked in some bulbs with only a few damaged cells; in others the outstanding lesion was neuronophagia of many mitral cells, with little or no meningeal or perivascular reaction. Although the virus was instilled in both nostrils, one of the olfactory bulbs frequently showed more extensive lesions than the other, and in five of sixteen monkeys in which both bulbs were in suitable condition for adequate examination, only one of the two appeared to be involved. The unilateral involvement of the olfactory bulbs in almost a third of the number of animals under the present experimental conditions clearly points to the necessity of studying both bulbs in each instance.

2. Covell, W. P.: Nuclear Changes of Nerve Cells in Acute Poliomyelitis, *Proc. Soc. Exper. Biol. & Med.* 27:927 (June) 1930. Hurst, E. W.: The Occurrence of Intranuclear Inclusions in the Nerve Cells in Poliomyelitis, *J. Path. & Bact.* 34:331 (May) 1931.

In order to throw more light on the nature and specificity of the described pathologic changes, it appeared desirable to study the olfactory bulbs of immune, convalescent monkeys resistant to nasal instillation of the virus suspensions. Four convalescent monkeys with residual paralysis that had previously been shown to be resistant to reinoculation were tested. Two of them had their primary infection by the nasal route three and one-half months, one by the intracerebral three and one-half months and another by the same route two and one-half months previously. After receiving virus intranasally, as a result of which control monkeys instilled simultaneously succumbed with poliomyelitis, they were killed two, four, five and seven days after instillation and their olfactory bulbs examined. None of the lesions just described were detected in any of them, thus yielding additional evidence that

Fig. 3.—Transverse section of olfactory bulb of monkey succumbing to experimental poliomyelitis eight days after nasal instillation of virus. Note dense cellular infiltration at *a*, perivascular cuffing at *b*, aggregate of inflammatory cells in glomerular region at *c* and neuronophagia of mitral cells at *d*.  $\times 40$ .

these pathologic changes are the result of active infection of the olfactory bulbs with the virus of poliomyelitis. It also became apparent that three and one-half months after infection by way of the nose the lesions observed during the acute stage may have disappeared, leaving evidence only of reparative changes.

That these pathologic changes may serve to indicate the portal of entry of poliomyelitis virus became evident from an examination of the olfactory bulbs of thirteen monkeys succumbing to the experimental disease induced by intracerebral, subcutaneous, intra-ocular and intrasciatic inoculation. Although the disease had been purposely allowed to run its full course in these monkeys, the olfactory bulbs appeared entirely normal. It is

Fig. 4.—Mitral cell amid smaller cells of internal granular layer in normal olfactory bulb.  $\times 1,000$ .

clear, therefore, that virus introduced directly into the brain or reaching the central nervous system by nerves other than the olfactory fails to induce the characteristic lesions in the bulbs. Recently it has been suggested by several investigators<sup>3</sup> that when large amounts of poliomyelitis virus are injected intravenously it may, after being eliminated on the nasal mucosa, invade the central nervous system by way of the olfactory nerves. The olfactory bulbs of three monkeys succumbing to poliomyelitis after intravenous injection of the virus were examined, and while typical lesions were found in one case there was none in the other two. These results indicate that virus from the blood stream can reach the central nervous system not only by way of the olfactory nerves but also by other pathways.

Although most investigators, and notably Flexner, believe that the nose is the natural portal of entry of the virus in man, others maintain that under certain conditions the gastro-intestinal route may supply the pathway for invasion of the virus. That postmortem

examination of the olfactory bulbs can supply valuable data regarding this question is evident from the results presented in this communication. Yet, as stated by Faber<sup>4</sup> in his review of work done on poliomyelitis up to 1933, "Little or no attention appears to have been devoted to the pathology of the olfactory bulb in poliomyelitis. It is a familiar fact that, unless special care is observed, the olfactory bulb, firmly attached as it is by the numerous olfactory nerves, is likely to be torn off when the brain is removed at necropsy, and so fail to be examined. This is the only explanation that occurs to me for the uniform failure to note either the macroscopic or microscopic appearance of the structure in the protocols available in the literature. Harbitz and Scheel briefly note in one case that the olfactory bulb was normal—the only instance in which I have found it mentioned."

Since then only the work of L. W. Smith,<sup>5</sup> reported in 1934, has come to our attention. This investigator studied microscopically fifty-six olfactory bulbs from about forty cases<sup>6</sup> of human poliomyelitis and stated that this examination "has shown a surprisingly small

amount of pathological change. There has frequently been edema and congestion, harbingers of more extensive damage, but in less than a fourth of them do the

6. Smith, L. W.: Personal communication to the authors.

characteristic cellular infiltrative changes, as seen in the ganglia and nerve roots, appear. Either any inflammatory reaction in these organs is extremely short lived, unlike the lesions of poliomyelitis elsewhere in the central nervous system, or the virus passes along these structures without leaving its identifying signature. A third possibility, which strikes us as more logical, in view of the essential difference in the nature of the pathological lesions, is that the olfactory bulb in human beings is not necessarily as frequent a pathway for the

Fig. 6.—Advanced neuronophagia in mitral cell layer of olfactory bulb eight days after inoculation.  $\times 684$ .

virus as is commonly held, and that nerve roots elsewhere are equally important portals of entry, possibly indirectly by way of the blood stream to their ganglia.”<sup>5</sup> Our own investigation shows that in experimental poliomyelitis the inflammatory reaction is not short lived and that the virus does not pass through the olfactory bulbs without producing characteristic changes. The third possibility just quoted should therefore receive careful consideration; and further studies on human material, particularly in the light of the nature of the bulb lesions in experimental poliomyelitis and the frequency of apparently unilateral involvement, should be of distinct aid in establishing the portal of entry of poliomyelitis virus in man.<sup>7</sup>

#### SUMMARY

1. The virus of poliomyelitis produces characteristic lesions in the olfactory bulbs of rhesus monkeys when it invades the central nervous system by way of the olfactory nerves.
2. These lesions are absent when the invasion of the central nervous system is by other pathways.
3. Postmortem examination of the olfactory bulbs may therefore serve to indicate the portal of entry of the virus under natural conditions.

Sixty-Sixth Street and York Avenue.

7. The authors are at present collecting a series of olfactory bulbs from cases of human poliomyelitis and would greatly appreciate the cooperation of pathologists who would send such material for study.

## PLANTAR WARTS, FLAPS AND GRAFTS

VILRAY P. BLAIR, M.D.  
JAMES BARRETT BROWN, M.D.  
AND  
L. T. BYARS, M.D.  
ST. LOUIS

Foot discomfort may vary from an intermittent annoyance to a real calamity, depending on its intensity and also on the occupational and social status of the individual. A nail or a pebble inside the shoe can make normal walking next to impossible; likewise can a plantar wart or a residual hard scar if located at a bearing point. Further, prolonged use of an unnatural stance can apparently lead to secondary changes, which may be persistently annoying long after the primary cause has been removed. After successful treatment of the wart or its local sequelae, the patient may still remain crippled. An antecedent static fault has been suggested as one, or a contributing, cause, but in our limited experience the static changes appeared to be secondary rather than primary.

Plantar warts are not of rare occurrence, and their clinical behavior and therapeutic response might suggest that they are not all of similar origin. A rather common tendency to recurrence or multiplication after a surgical excision also suggests the possibility that at least some are infectious in origin. Some prove very sensitive to radium or roentgen therapy, while others of exactly similar appearance are resistant. Some disappear spontaneously, as may happen in other parts of the body or after the prolonged use of salicylic acid held in contact with adhesive plaster.

Radium or x-rays in doses well within the limits of safety is probably the best tentative plan of treat-

Fig. 1.—A young woman in the better station of life had a plantar wart appearing seven years ago, which had been treated repeatedly with radium and x-rays. In November 1931 she presented herself for treatment for the wart from which she supposed she was still suffering. A, a mass of scar at the site of the original wart. For fear that some of the wart elements might still exist, this scar was removed with the cutting cautery and at a later period (April 1932) a pedicle flap with its base behind the small toe was raised from the loose sole tissue between the bearing surface of the ball and the toes. This flap was swung backward into the defect, which had been refreshed. Note in A the persistence of the normal skin under the ball of the great toe, while in B is shown a large callus, recently pared, which appeared sometime after the transfer of the flap. Since the patient lived in a distant city, it was difficult to get a satisfactory orthopedic follow up. Somewhat recently she came under the care of Dr. Ellis Jones, who, from her reports, seems to have been able to give her perfect relief by proper foot padding.

ment, but excessive irradiation can be quite disastrous. Too often a patient seeking relief has for years been

Read before the Section on Surgery, General and Abdominal, at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 15, 1936.

under treatment for a wart that had long since disappeared, the aggravated symptoms being due to pressure of a weight bearing bony point on a deeply penetrating radiation scar or a callus due to secondary static changes. If the wart has not entirely disappeared a month or six weeks after a moderate dosage of radiation, one of two plans should be followed: One plan is knife excision and immediate suture; the other

Fig. 2.—The foot of a very heavy professional man, who had been almost totally incapacitated because of a plantar wart on the middle of the ball of the foot. It was treated with x-rays. *A*, an acute dermatitis which appeared some weeks after the patient had gone to a seashore resort. For some rather inexplicable reason, a wide surgical removal of the damaged area was made in the acute stage of the inflammation. The destruction of the fat pad down to the bone left the man almost unable to walk. *B*, correction by the transplantation of a pedicle flap of skin and fat from the calf of the right leg. This has given a comfortable bearing pad, but the skin has been slow to respond to environmental change and for a long time he wore adhesive plaster for its protection.

is accurately limited actual cautery destruction. The latter is simple and effective and, if the wart is not large, is ordinarily neither long confining nor followed by a painful scar, provided the surrounding skin and underlying fat have been spared. This has been our procedure of choice.

A reaction from excessive irradiation may result from oversensitivity of the individual, overdosage, or both, but ordinarily it will not have been pushed beyond production of a dermatitis. This, although painful, will usually, if not further irritated, subside spontaneously, possibly leaving a small area that will require but relatively simple surgical repair. The most crippling results have come from ill advised treatment of a postirradiation disturbance. Here, as elsewhere, acute radium or x-ray burns are decidedly intolerant of a wide range of chemical applications. Among these is bromine, which is an ingredient of certain analgesic applications that have proved to be quite soothing in various other conditions, but here its use has been followed by great aggravation, even causing massive slough of the inflamed area. Another unfortunate procedure is the early removal of the skin and fat pad from the inflamed irradiated area. Under these circumstances patients have suffered for years before the necessity for an extensive repair has been recognized.

A distressing "cornlike" scar that may follow the primary wart destruction should be completely excised, and if the defect is small it can be closed by skin suture, perhaps with some drawing together or switching of the fat pad. For larger defects that cannot be corrected by these simpler plans, a pedicle flap which includes skin and part thickness of the pad can be switched from a non-weight bearing surface of the sole, either

of the front of the ball just behind the toes or of the inner half of the central part, and the resulting defect is immediately covered by a skin graft. If the skin alone is missing but with sufficient fat pad persisting, this can be covered with a thick split graft. Even when there has been a very large loss of both skin and pad, as occurs from fire burns, or accidents caused by the automobile or machinery, a split skin graft placed directly on the muscles or granulations will effect immediate coverage, and the subsequent use of a fine meshed sponge rubber insole will serve as a partial, but more or less practical, substitute for the lost fat pad. In the few instances in which I have transferred a fat-skin flap from the calf of the other leg to the bearing surface of the sole, the result has proved somewhat disappointing. The leg fat lacks the tough resilience of the normal sole pad, and the epithelium of the transplanted skin itself fails to harden to its new task. In one case I achieved my end by constantly protecting the transplanted skin with adhesive plaster. In another, a quite satisfactory final result was obtained by excising two persistent "trophic" ulcers, and immediate split skin grafting to the underlying scarred fat of the transplanted leg flap. Because of the resistant "bearing" surface that develops on the outer dorsal surface of an uncorrected "clubfoot," I have sought to transfer large pedicle flaps from this area but have encountered real difficulty in preserving the circulation even after delaying the transfer of the flaps.

The crippling or painful calluses that are apt to develop and stubbornly persist in some other area of plantar skin after a localized wart has been controlled may prove most embarrassing. I am beginning to be a little uncertain as to two points in their regard: the first is whether the persistence of the callus is entirely due to an acquired faulty position of the foot; the

Fig. 3.—The foot of a man who for some years had suffered from the painful scar of a cured wart. The small actual destruction of the foot pad was compensated for by undermining and shifting neighboring tissue, and the coverage was made with a split skin graft. This gave a very satisfactory result.

second, whether the conservatism that I have habitually exercised in the past has all been to the patient's best interest, the possibly fantastic doubt having arisen as to whether the tendency to callus growth can always be eliminated by partly relieving the pressure on that spot. My belief is that in every case of crippling callus the

patient should be given the benefit of the most skilful orthopedic treatment available; but if these hangover cases do not get relief by corrective shoeing within a reasonable time, I can at present see no reason for not eliminating the callous spot by excision and immediate switching of a fat-bearing planar flap, a plan that has proved most successful in the treatment of certain painful plantar scars.

Grand Avenue and Olive Street.

#### ABSTRACT OF DISCUSSION

DR. ELLIS FISCHER, St. Louis: Irradiation is the accepted method of treatment. As the authors have emphasized, the first consideration in using radiation is not to do damage. My experience has been limited to the use of radium in the following manner: 50 mg. of radium element contained in 12.5 mg. steel alloy needles, placed within a 1 mm. brass or silver capsule, and around that approximately a millimeter of rubber. Then a fenestra is made through a millimeter of lead and the bottom of that fenestra covered with a millimeter of rubber. The fenestra is just large enough to contain the wart. One treatment of two hours' duration with this applicator has usually been sufficient, and in even those cases previously treated by x-rays a dangerous reaction has never been observed. Of twenty-eight private cases treated in this manner, twenty-one responded favorably to one treatment. But one must not be in too much of a hurry. The average patient

Fig. 4.—The transplantation of a leg flap under the ball of the foot and the heel to replace scars from a deep burn. Note three trophic ulcers, which subsequently developed with use and which were extremely persistent. The foot was finally made well and useful by removing these ulcers, including border and base down to the soft scar in the underlying fat pad and applying split skin grafts.

may be expected to have relief from pain in approximately three or four days, but the wart does not disappear until sometime later, usually in about two weeks. However, occasionally a

Fig. 5.—A deep loss on the outer and under surface of the heel. To remedy this an attempt was made to prepare a delayed flap from a non-bearing part of the foot. This was not used because of impaired circulation. The scar covering the original defect was replaced by a split skin graft, and a sponge rubber pad has made a very satisfactory substitute for this partially lost fat pad.

patient will go four weeks before stating that he no longer notices the wart. I wait four weeks. If the wart is still present after four weeks' time the dose is repeated. Of the twenty-eight cases it is known that fifteen had satisfactory results. There were satisfactory immediate results in ten

additional cases but there has been no long follow up. Plantar warts may occur in a callous area. I do not know whether it is the callus or the wart that is causing the pain. By taking a stiff blunt probe and pressing on the black wart and then around the wart on the callus, one can easily obtain differentiation. If pressure outside the wart causes pain, one must realize that the callus may have a good deal to do with it; then one must differentiate between the pain from the callus and the pain from a possible underlying periostitis. The latter is the bugbear of all this treatment, because patients who have a periostitis from long pressure over the head of the metatarsal bone are not going to be cured by any method of local treatment of the skin condition. The molehill has now become the mountain, the proper handling of which has been so ably presented by Dr. Blair and his co-workers.

DR. JOSEPH J. ELLER, New York: I agree with the authors that only safe doses of radiation should be used on account of the sequelae which may occur from more destructive measures. With the dosage of from 80 to 100 milligram hours of gamma radiation to the square centimeter of tissue, plantar warts should undergo involution. Plantar warts are not true new

Fig. 6.—The foot of a working man with an alcoholic neuritis and anesthesia which accounted for his standing on the floor of a partially cooled furnace long enough to burn his feet. This caused wide destruction of the skin and pad in the balls of both feet. On the foot shown, repair was made by shifting a fairly large flap from behind the toes to beneath the heads of the metatarsal bones. The resulting defect from the switching of the flap was covered with a split skin graft. On the left foot the destruction was much more extensive. The bare area was covered with a split skin graft placed on the plantar fascia, and a sponge rubber pad was used.

growths. They are due to an infectious virus. From 60 to 70 per cent of these lesions will disappear on irradiation with radium or roentgen rays. Many dermatologists in this country now treat plantar warts by means of 2,500 and 2,800 roentgens unfiltered. In other words, they use the warty excrescence as a filter, and with that dosage used in one treatment, a good many of the lesions will disappear. If they do not disappear, there is a problem. I have found that whenever surgical measures are used following irradiation of skin tissue a keloidal scar results, and while the wart may be removed either by excision or by electrocoagulation, a keloidal scar formed as a secondary growth is just as painful as the original wart. The patient and the physician frequently think erroneously that there has been a recurrence. One has to resort to small safe filtered doses of radiation to dissolve that keloid. Excising a keloid does not make it disappear. It only results in a larger one. I agree with the authors that the only treatment for post-irradiation injury is excision, care being taken to preserve the fat pad; later, to counteract any hypertrophic scar, small doses of radiation should be given. Another thing which dermatolo-

gists have observed is that plantar warts, when destroyed by electrocoagulation, frequently result in very small slow-healing ulcers. With this therapy one must not promise that the patients can get back on their feet in less than three weeks. There is very little that one can do to hurry the healing. Perhaps in these cases after destruction the best treatment would be an immediate plastic repair, without waiting for slow granulation and healing, which sometimes takes even as long as six weeks.

DR. VILRAY PAPIN BLAIR, St. Louis: Dr. Eller brought out the necessity of giving orthopedic care of the foot after the wart has been cured. There is little I know less about than scars, but I do think I know this much, that anything that will put lateral tension on the wound will tend to make a bad scar. If the loss is limited to the skin, a skin graft will suffice. If the defect is too large to permit the sliding in of a bordering fat pad, the switching of a pedicle flap of skin and fat pad will probably be the safest plan. When heat destruction is indicated, I use a fine platinum, electrically heated, cautery point. In a much treated case, knife removal will probably be the better, as it is likely that the wart is already cured and the flap can be switched in place at the same sitting.

## ULCERATIVE LESIONS OF THE SKIN IN LYMPHOGRANULOMA INGUINALE

MAX S. WIEN, M.D.  
AND  
MINNIE OBOLER PERLSTEIN, M.D.  
CHICAGO

Ulceration of the skin as a part of the syndrome of lymphogranuloma inguinale has not received much notice in the discussion of the clinical manifestations of this disease.

Huguier<sup>1</sup> in 1848 described esthiomene as a chronic hypertrophy and ulceration of the vulva which may be associated with similar involvement of the vulvo-anal area, rectal ulceration or stricture. In the majority of his cases there was also infiltration of the inguinal lymph glands. He subdivided his entity into four main clinical groups: a hypertrophic vegetative type, an elephantiasic type, a type characterized by the formation of fistulas, and an ulcerative type.

Fournier<sup>2</sup> in 1873 described the occurrence of a syndrome of indolent edema of the vulva which was frequently associated with inguinal lymphopathy. He believed that it was syphilitic in origin but distinct from his "syphilome anorectale." Ulceration of the vulva is not mentioned in his description.

In 1896 Koch<sup>3</sup> reported twenty cases, all of which presented a syndrome which he designated as "ulcus vulvae chronicum elephantiasicum." All these patients had associated pathologic conditions of the inguinal lymph glands. He summarized the symptomatology as follows:<sup>4</sup>

The labia majora were the seat of more or less marked thickening, with ulceration, . . . rather less commonly the labia minora and clitoris were affected, . . . the skin had a bluish red color and was ulcerated; sometimes . . . the

mons, the commissure and perianal region were involved in the infiltrative process. . . . Ulceration might occur in any part of these infiltrated tissues but was most common at the commissure, the opening of the urethra, on the inner surface of labia minora and clitoris. The ulcers in shape were often irregular or dentated; with a yellowish shiny base, callous thickened steep sides, with sometimes undermined edges, and showed as a rule no tendency to epitheliation, though sometimes healing on one side and extension on another was noted. Perforation of the nymphae, fourchette, or urethrovaginal and rectovaginal walls might occur, with the formation of fistulae; or there might be greater destruction of tissues, with the production of a cloaca, limited by portions of infiltrated skin and mucous membrane; rectovesical fistula might also be produced. The rectum might be severely involved, the mucous membrane of the anal canal altered to form a rigid ulcerated tube, with an ulcerated anal opening, sometimes also the seat of papillomata and extroversion. In some cases a rectal stricture was also present.

Koch believed that this condition was not due to syphilis, tuberculosis or *ulcus molle* and had no suggestions to offer concerning its etiology.

Taussig<sup>5</sup> in 1922 named the condition hypertrophic ulcerative chronic vulvitis of undetermined etiology.

Jersild<sup>6</sup> in 1920 was impressed by the frequency of the coexistence of elephantiasis vulvae and rectal stricture and named this clinical association the genito-anorectal syndrome.

Following the advent of the Frei test,<sup>7</sup> Frei and Koppel<sup>8</sup> in 1928 established their cases of genito-anorectal syndrome as lymphogranuloma inguinale (Durand, Nicolas and Favre<sup>9</sup>).

In a series of 500 patients with lymphogranuloma inguinale, we have observed twelve cases of ulceration. We present the detailed clinical reports of three of these patients together with bacteriologic and histologic studies. These three cases illustrate the types of clinical ulceration that may occur in lymphogranuloma inguinale:

1. Ulceration of the skin only—lymphitis (case 1).
2. Ulceration of the skin secondary to a previous lymph gland involvement (case 2).
3. Ulceration developing on an existing esthiomene (case 3).

### REPORT OF CASES

CASE 1.—*History*.—A Negress, aged 40, gave a history of rectal pain and itching associated with constipation of twenty-three years' duration. Eight years before her admission to the hospital a rectal operation was performed, since which time she has had pencil-sized stools and a purulent rectal discharge. During the preceding five months she had pruritus vulvae associated with pain and burning on urination. Her general health had been good. Her husband was well and had no similar complaint. Physical examination was essentially negative except for the genital pathologic condition (fig. 1). The perineal tissues were of firm cartilaginous consistency with induration of the perianal and adjacent crural areas. There was a fissure extending from the vagina to within 1 cm. of the anus, almost forming a cloaca. On the inner surface of both labia minora was a superficial ulceration which extended on to the vaginal mucosa and adjacent perineum. The margins of the ulceration were serrated and soft. The base of the ulcer

was bright red, smooth and painful. There were no nodules on the base and there was little bleeding on trauma. The rectal mucosa was nodular and there was a rectal stricture about 3 cm. from the anal orifice.

The Frei test was positive; the dmelcos, blood Wassermann and Kahn tests were negative. Darkfield examination was negative.

Bacteriologic examinations revealed many bacilli and cocci but no Donovan bodies or Ducrey bacilli.

**Histologic Examination.**<sup>10</sup>—The specimen consisted of a small piece of skin with an irregular ulcer. The floor of the ulcer was formed by a very cellular granulation tissue, which was

composed of round cells and polymorphonuclear leukocytes and of capillaries with prominent endothelial cells. Plasma cells were numerous, and dense infiltrations extended beyond the ulcer into the papillary and subpapillary layer, which was covered by an intact epithelium. The rete pegs were elongated and in the basal portions became widened and enclosed hyalinized epithelial cells. In many places polymorphonuclear leukocytes invaded the rete pegs.

**CASE 2.—History.**—A Negress, aged 20, was seen in June 1935 with the following history: One year previously she had a painful "blister" on the vulva, which slowly enlarged. Four weeks after the appearance of the vulvar lesion the

Fig. 1.—Ulceration of the inner surface of the labia minora.

right inguinal area became swollen and painful; later the left inguinal area became involved. The lymphatic glands drained spontaneously and large ulcers developed in the right inguinal area. Her general health had been good. The essential pathologic changes on examination were limited to the genital area (fig. 2). The right inguinal area was the site of two quarter-sized (24 mm.) superficial necrotic painful ulcers with a similar, larger lesion in the left inguinal region. The labia were markedly endematous. These ulcers were clinically identical, having sharp margins, rolled edges and a clean hemorrhagic base. Adjacent to the ulcer on the right inguinal area were two puckered, scarred bands.

The Frei test was positive, the Ito-Reinstierna reaction was negative, smears from the vulvar ulcer were negative for gonococci, and the blood Wassermann reaction was positive. Bacteriologic examinations were negative for Donovan bodies, Ducrey bacilli and tubercle bacilli.

**Histologic Examination.**—The specimen taken from the ulcer in the inguinal region showed a small piece of skin with a moderate acanthosis of the epidermis. The papillary layer of the cutis was infiltrated by lymphocytes and plasma cells and the infiltrations followed the capillary blood vessels into the subpapillary layer. In this region the infiltrations became more extensive and had the tendency to fuse together. Between the lymphocytes there were swollen histiocytes and plasma cells, and the adventitial cells of adjacent capillaries often joined with one another to form a loose cellular reticulum. In the reticular zone of the cutis the infiltrations again broke up into perivascular round cell accumulations similar to the picture seen in the papillary layer.

Treatment consisted in the intradermal injections of Frei antigen<sup>11</sup> every three days for a period of three weeks. The ulcers in the inguinal areas involuted completely, and the vulvar ulcer was almost healed at the end of this time. Antisyphilitic treatment was then instituted. There was complete healing of all ulcers by September 1935.

**CASE 3.—History.**—A Negress, aged 32, was first seen in March 1935. In 1932 a painful nodule appeared on the right vulva three weeks after intercourse. The nodule ulcerated and was associated with a swelling of the labia. The right inguinal region subsequently became swollen and tender and the gland ruptured spontaneously and drained slightly for about one year.

There was bilateral shotty inguinal adenopathy. The vulva was hypertrophic. Between the labium majus and minus was a crater-like ulcer 2 cm. wide and 1 cm. deep with red and granular walls. The base was yellowish gray with a moderate yellowish exudate (fig. 3).

The Frei test was positive; the dmelcos, blood Wassermann and Kahn tests were negative. Darkfield examination was negative.

Bacteriologic examinations revealed many bacilli and cocci but no Donovan bodies or Ducrey bacilli.

**Histologic Examination.**—The specimen consisted of a small piece of skin with an ulcerated area, in the region of which the epidermis was missing. The floor of this ulcer consisted of a granulation tissue which originated from the subpapillary layer of the cutis and was very cellular. It contained thick-walled capillary blood vessels at regular intervals and between and about these blood vessels were dense accumulations of small and medium sized round cells with scanty cytoplasm. Between the lymphatic cells were found a few plasma cells and polymorphonuclear leukocytes, and near the free surface of the ulcer the leukocytes became more abundant. The capillaries had swollen endothelial cells, and attached to the outer aspect were adventitial cells which were prominent and extended between the adjacent round cells. The infiltration was sharply circumscribed and in the surrounding cutis loose accumulations

Fig. 2.—Ulceration of the skin on a preexisting suppurating inguinal lymphadenopathy.

of lymphocytes and histiocytes were seen which were scattered between the connective tissue bundles or centered about small blood vessels.

#### BACTERIOLOGY<sup>12</sup>

The bacteriologic flora from nine cases of lymphogranuloma inguinale and one of granuloma inguinale was examined. The surface of the lesions was well washed with sterile saline solution, sterile gauze sponges

11. Wien, M. S., and Perlstein, Minnie O.: The Intradermal Treatment of Lymphogranuloma Inguinale, Arch. Dermat. & Syph. 28:42 (July) 1933; Brit. J. Dermat. & Syph., to be published.

12. The bacteriologic examinations were made by Dr. Virginia Fisher of the Department of Bacteriology, University of Illinois College of Medicine, Dr. L. L. Arnold, director.

10. The histologic examinations mentioned throughout this article were done by Dr. R. H. Jaffé of the Cook County Hospital.

being used. Direct smears were studied by means of the Gram stain, and darkfield examinations were made. A small piece of tissue was curetted from the lesions and emulsified in a small amount of sterile saline solution. This material was then used for the inoculation of the following mediums: plain agar, blood agar, honey agar, Endo agar, semisolid dextrose agar and

cutaneous surface. Chief among these are chronic chancroidal infection, granuloma inguinale, ulcerative tertiary syphilis, tuberculosis cutis, gonorrhea, ulcus vulvae acutum (Lipschütz), ulcus vulvae simplex chronicum, traumatic ulcer and epithelioma.

Chronic chancroidal infection is a contagious and auto-inoculable ulceration caused by the streptobacillus of Ducrey. The lesions are usually multiple, painful, dime-sized (18 mm.) ulcerations that have perpendicular undermined edges, a dirty yellow base and a foul smelling discharge. The associated inguinal adenitis or bubo is a unilobular lesion which drains a thin foul smelling pus containing the Ducrey bacillus. The dmelcos and Ito-Reinstierna reactions are positive.

Granuloma inguinale is a superficial ulceration of the skin produced by Donovan bodies.<sup>13</sup> The ulcers are contagious and auto-inoculable and present numerous shiny verrucous vegetating nodules of granulation tissue at the margins and dispersed throughout the base of the ulcer. This ulceration after healing produces a dense white contracting scar tissue. The process is painless and, as a rule, unaccompanied by adenopathy.

Ulcerative tertiary syphilis results from the coalescence of groups of discrete "punched out" ulcers that tend to assume an arciform or annular configuration and heal spontaneously, producing a thin white atrophic scar with hyperpigmented borders. The serologic reaction of the blood is positive and the condition involutes with antisyphilitic treatment.

Tuberculosis cutis of the ulcerative or gummatous variety presents irregular painful ulcers and fistulas, the base of which is uneven and covered with yellowish

brain broth. These were incubated at 37.5 C. for from twenty-four to forty-eight hours and the organisms studied by smears and additional cultural methods.

The most regularly occurring organisms are shown in the accompanying table. It should be observed that no Spirochaeta pallida and no Ducrey bacilli were found in any of the lesions; also that in spite of the location of the lesions in the inguinal, vaginal and anal regions, B. coli appeared very rarely. Both Staphylococcus albus and aureus were found; the streptococci were usually of the hemolytic variety.

Organisms other than those shown in the table were found in some specimens but with no regularity.

It seems reasonable to conclude that the organisms found are most probably secondary invaders which may usually be found in necrotic lesions.

DIFFERENTIAL DIAGNOSIS

The ulcerative lesions occurring in lymphogranuloma inguinale are superficial in character, irregular in outline and variable in size and contour. The normal skin may merge abruptly with the ulcer or form a thin overlapping cordlike band with a tendency to serration. The walls of the ulcer are usually of a shallow, shelving type. The base of the ulcer is vivid red, shining, and of a smooth velvety texture. There is an absence of verrucous nodules or granulations in the base or margins of the ulcer. A thin, clear mucoid secretion may cover the lesion. In neglected cases this may assume a purulent character. The ulcer spreads by peripheral extension, is not auto-inoculable and shows no tendency to spontaneous healing. The lesions are painful on palpation. The Frei test is positive. Histologic examination reveals a nonspecific microscopic picture of tissue suppuration with ulceration of the skin and a predominance of plasma cells in the infiltrate. No organisms are seen in the stained sections.

This condition must be differentiated from those entities associated with superficial ulceration of the

Fig. 3.—Ulceration developing on existing esthiomene.

granulation tissue. Smears of the discharge or stained histologic sections reveal the tubercle bacilli. The histologic picture reveals a tuberculous architecture.

Ulcus vulvae acutum (Lipschütz<sup>14</sup>) is a painful recurrent ulceration of the external genitalia. The

ulcers are superficial, painful and not auto-inoculable and they heal spontaneously. *B. crassus* is usually present in the ulcers.

*Ulcus vulvae simplex chronicum*<sup>15</sup> occurs in old prostitutes and affects the fourchette. It has no tendency to spread and is not associated with inguinal adenopathy, hypertrophy of the vulva or stricture of the rectum. The Frei and dmelcos tests are negative.

Gonorrheal infection may produce a vulvitis associated with erosive lesions, the margins of which may be variable and the base a dusky red and with a granular surface. Smears are positive for gonococci.

Traumatic ulcers have a characteristic, irregular or fissured form with a preceding history of injury. The lesions heal with marked rapidity.

Epithelioma in the genitocrural region is characterized by the occurrence of a granulomatous new growth in which the ulceration occurs as a secondary phenomenon. The lesion is slow in growing, often with rolled pearly margins, and the nodules are friable and bleed freely. Histologic examination reveals the characteristic changes of a malignant condition.

#### COMMENT

Chevallier and Bernard<sup>16</sup> studied the histologic aspects of lymphogranuloma inguinale and concluded that the classic poradenitis is due to the association of two processes, an adenopathic and a cutaneous. The adenopathic phase consists of a number of gummas separated from the upper hypoderm by a band of healthy tissue. The progression of these gummas toward the surface of the skin can be seen in some sections. The cutaneous phase involves the upper part of the hypoderm and is accompanied by lymphangitis. At times the cutaneous ulceration develops before the deep gummas have reached the skin. These writers believe that there may logically exist either a pure cutaneous or a pure lymph gland form in addition to the classic forms of combined lymph gland and skin involvement. The reports in the literature make little mention of the ulcerative phase (cutaneous form) of this complex syndrome.

The cases reported demonstrate the three types of clinical ulceration that may occur in lymphogranuloma inguinale and illustrate the histologic aspects mentioned by Chevallier and Bernard.

The cutaneous phase (lymphitis) is clinically and histologically demonstrated by case 1. This type of involvement is analogous to that previously reported, among others, by Wien, Perlstein and Neiman,<sup>17</sup> and by Pinard and Fiehrer<sup>18</sup> as occurring in nodular form with the formation of secondary ulcerative plaques in the skin. In this instance the epidermal lymphatics and those of the upper part of the hypoderm are affected with the virus of lymphogranuloma inguinale, and an inflammation results that manifests itself as a superficial ulceration of the skin.

The occurrence of ulceration of the skin secondary to involvement of the underlying lymph glands—the adenopathic phase—is demonstrated by case 2. Similar

lesions may occur in males, as reported by Midana.<sup>19</sup> We have seen two men who presented inguinal adenopathy associated with superficial ulceration of the abdomen and inguinal regions.

The occurrence of chronic hypertrophy and ulceration of the vulva (esthiomene-Huguier<sup>1</sup>) is demonstrated by case 3. This case is a classic example of the entity first described by Huguier and may be associated with rectal stricture giving rise to the genito-anorectal syndrome of Jersild.

#### SUMMARY

1. Twelve cases of ulceration of the skin occurring in our series of 500 cases of lymphogranuloma inguinale were observed and are reported with clinical, bacteriologic and histologic records of three cases. Two men presented ulceration of the skin in association with inguinal adenitis.

2. Three types of ulceration of the skin are demonstrated by the cases described:

(a) Ulceration of the skin only.

(b) Ulceration of the skin secondary to an existing lymph gland involvement.

(c) Ulceration developing on an esthiomene.

3. The bacteriologic flora of the ulcerations was thoroughly investigated. The organisms found were probably secondary invaders.

4. Histologic examinations of the ulcerations were nonspecific. There was a uniform picture of ulceration, fibrosis and plasma cellular infiltration.

5. We feel that cases of superficial ulceration in the skin, resistant to the ordinary or specific methods of therapy, especially when occurring in the genitocrural area, should be tested with Frei antigen, diagnostically and therapeutically, in order to rule out the possible relation of the ulceration to lymphogranuloma inguinale.

104 South Michigan Avenue—30 North Michigan Avenue.

#### ABSTRACT OF DISCUSSION

DR. C. C. TOMLINSON, Omaha: I find it difficult to accept the fact that the cutaneous ulcerative phase may exist independent of underlying suppurative lymphadenitis. Is it not possible that a few small nodes in the rectovaginal septum, the anorectal nodes of Gerota, or other lower pelvic nodes may be draining through small fistulas which cannot be detected on examination and which are responsible for the persistent cutaneous destruction, such as is exemplified in their case 1, and which they describe as lymphitis? Case 2 is portrayed by the authors as cutaneous ulceration secondary to underlying inguinal lymphadenitis. With reference to case 3 I would like to ask if it would not be possible, or even probable, that there existed an underlying suppurative process in the lymph nodes of the rectovaginal septum which was responsible for the granulomatous vulvitis referred to as esthiomene with ulceration. Although I do see the genito-anorectal syndrome occasionally in Omaha, I have not encountered persistent cutaneous ulceration as described by the authors. The chronic cases for the most part have presented as rectal stricture, perineal sinuses or esthiomene. We have difficulty in following individual cases for long. We do not have facilities for prolonged hospital observation, and the majority of our colored patients leave us when we exhibit what to them may seem undue interest in their condition. We have instituted intradermal Frei antigen treatment in several women with rectal stricture as a pre-operative measure (previous operations having failed to cure their stricture) but have not been able to hold these patients long enough to evaluate the therapy. I believe that in our early cases filtered x-ray therapy over the involved lymph nodes

has been of value and that intradermal Frei antigen treatment is also decidedly advantageous. At times it is difficult to find satisfactory early cases from which to make sufficient antigen to treat other patients. It is our intention to make virus culture antigen (J. T. Tamura, *THE JOURNAL*, Aug. 11, 1934, p. 408) in larger quantities than one can hope to obtain with pus-derived antigen, and to treat a series of cases with it.

DR. HARRY M. ROBINSON, Baltimore: May I sound a warning about the positive Frei test. It means past or present lymphogranuloma inguinale, but not every lesion that gives a positive Frei test is lymphopathia venerea. Even though a patient has a positive Frei test and a fluctuant bubo, the resultant pus is not accepted as a good antigen until it has been tested with known cases. In our groups of cases, my associates and I differ from the authors in that with a large Negro clinic we have found 1 per cent positive Frei tests in white persons and 60 per cent in Negroes (all of whom had syphilis).

DR. SAMUEL GOLDBLATT, Cincinnati: When multiple Frei antigens are used, one is likely to receive varying results on the same individual. We in Cincinnati have a habit of testing at the time for diagnosis with about fifteen different antigens. These are controlled by old tuberculin and bovine tuberculin. The antigens, most of which are made in the clinic from known cases, are also controlled by monkey brain antigen, which I obtained from Dr. Hellerström of Stockholm. It is not unusual to see varying degrees of positiveness with the first four or five antigens, one being four plus, two three plus, three one plus, four negative. In case 2, with clinically the same type of results, antigen 1 may be negative and antigen 5 positive and the others varying. In case 4 the antigens that previously varied may give the same result. I am at a loss to understand this phenomenon; I am simply reporting it as an observation. I can also confirm the fact that in colored patients 60 per cent positive Frei reactions are obtained as a routine. In a mixed group, almost equally white and colored in the Cincinnati workhouse, about 50 per cent of Frei tested groups report positive. It is not always possible in positive Frei reported cases to find evidence or history of the infection. Dr. Wien will probably remember a case which I presented at the last Cincinnati session of the Mississippi Valley and Central States Dermatological Society, a woman of about 50 who had a tremendous elephantiasis with sinuses involving the entire vulva and the right buttock. In this case all the Frei antigens had been repeatedly negative, although six years previously the woman had had clinically a definite papular syphilid; her Wassermann reaction at that time and on all repeated occasions had also remained negative. Tested with material taken from her own glands, the patient was negative. We have surgically excised with the electrocautery this entire area in two stages; the last stage, that of the buttock, is at present healing. We were never able to find a definite rectal stricture, although she has had very long attacks of serious diarrhea which may be a precursor of the stricture.

DR. PAUL A. O'LEARY, Rochester, Minn.: My experience has been quite the opposite of Dr. Robinson's in that all my cases of lymphogranuloma inguinale have been in white persons. Drs. Wien and Perlstein have furnished me with the diagnostic antigen, which has also been highly efficient therapeutically in our patients when the treatment was started early in the bubo stage. I wish to stress the point that we now have evidence that lymphogranuloma inguinale is a systemic disease and not solely a genital infection. In support of this contention the following complications may be cited: Cutaneous ulcerations of lymphogranuloma inguinale have been reported occurring elsewhere than about the genitalia; likewise I have seen on two occasions a follicular reaction on the skin, of the nature of an "id," in patients with acute signs of the disease. In addition to rectal stricture, the retroperitoneal lymph glands may become involved in the early cases and produce difficult differential diagnostic problems. Perhaps the authors could give some figures on the relative incidence of chancre, chancroid and the early lesions of lymphogranuloma inguinale. I ask this question because patients with a chancroid are now seldom seen in our clinic.

DR. ANDREW L. GLAZE, Birmingham, Ala.: A case of lymphopathia venerea in a petty officer of the navy, retired,

was observed this spring. Chronic superficial ulcerated lesions of the skin of four years' duration were present. The scrotum was involved. Much of the skin of the glans penis was destroyed. Frei tests were done with different antigens, mouse brain and antigens from human sources; all were strongly positive. The histologic picture was consistent with the disease in question. Bacteriologic and serologic studies as well as therapeutic tests aided in ruling out other possible disorders.

DR. MARION B. SULZBERGER, New York: Because the old name of lymphogranuloma inguinale had led to confusion with lymphogranuloma on the one hand and with granuloma inguinale on the other, Dr. Wolf and I thought it would be better to call this disease by some other name. And so in 1932 we suggested the name of lymphopathia venerea (*Lymphopathia Venerea*, *Brit. J. Dermat. & Syph.* 44:192 [April] 1932). I was fortunate enough to be able to perform the first Frei tests in the United States, using Frei "antigen" which I had brought with me from Europe. After performing this test, which I had learned from Prof. Walter Frei in Breslau, Dr. Wolf and I in 1931 reported the first positive tests on patients in New York and submitted this report to *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*. *THE JOURNAL* sent back this brief report with the statement that the disease and test discussed in our communication were not of sufficient interest to the general medical profession to warrant its publication in its pages. I recount this fact merely to show how rapidly the American medical public has learned about this disease; for my story shows that both the disease and the test were unrecognized here only a few years ago (1931) and I think that we need not emphasize how much real interest has since been aroused in this country by the Frei test and by the possible unification of all these different manifestations, by means of its employment. The interesting point is that daily new manifestations are being found which can be regarded as probably due to this infection. I should like to mention here two possible further additions: One is colitis, as probably simply due to this virus, occurring without rectal strictures, and therefore not of secondary nature. Dr. Joseph Goodman is reporting a short series of such cases from Johns Hopkins. Second, I believe that there is some evidence that there is a sarcoid form of this disease. I have seen two cases which were clinically and histologically characteristic of lymphopathia which had what appeared to be concomitant sarcoid lesions of the bones (i. e., cystic changes in the bones). In these cases there was no evidence of any other type of infection that could account for the sarcoid bone lesions.

DR. MAX S. WIEN, Chicago: To answer Dr. Tomlinson's question: The cutaneous phase may exist with gland involvement elsewhere in the body, but it is not essential that there be gland involvement contiguous to the areas of cutaneous ulceration. According to the concept of Chevalier and Bernard, histologically, in the pure cutaneous phase, one sees no evidence of involvement of the lymphatic network of the deep cutis; there is involvement high up in the cutis and involvement of the lymph spaces of the epidermis, whereas in the so-called adenopathic phase these deep glandular changes are not seen. In our first case the cutaneous ulceration occurred on the labia minora and labia majora, in areas apart from the inguinal gland involvement present. There was a lymphitis or lymphangitis of the involved sites. As to the specificity of the Frei test, commented upon by Dr. Robinson, there is no question in the minds of those who have done a large number of Frei tests about its specificity. We have done from 2,500 to 3,000 Frei tests and we feel that it is specific. One may get a positive Frei test with an asymptomatic lymphogranuloma inguinale just as one may get a seropositive asymptomatic syphilis. Positive Frei antigens have been produced in our case of lymphitis from maceration of the skin. Dr. Goldblatt brings up the point about Frei antigen giving a variable reaction. That is true of any antigen. It is an inherent property of antigens to give variable reactions. Hellerström brings out this fact and mentions that some antigens may be universal, giving the same type of reaction in all patients. Wherever there is lymphatic structure or lymphatic drainage, the virus of lymphogranuloma inguinale may go directly or by retrograde extension. We have seen erythema nodosum and erythema multiforme in the course of the disease. In testing a large series of cases

that were diagnosed chronic chancroidal infection with dmecos antigen, we got one positive reaction proving that most of these cases were not chancroid. We feel that a large number of cases of chronic chancroidal infections which have not responded to the accepted treatment for chancroid will in the future be proved to be cases of the cutaneous phase of lymphogranuloma inguinale. As to the term lymphopathia venerea, we referred to Dr. Sulzberger's work in our previous papers and we are grateful to him for first calling our attention to this disease. We have adhered to the name lymphogranuloma inguinale to avoid confusion in the literature, because that is the name more frequently used. Ulcerative colitis and proctitis have occurred in our experience.

## PARA-AMINO-BENZENE-SULFONAMIDE AND ITS DERIVATIVES

EXPERIMENTAL AND CLINICAL OBSERVATIONS ON  
THEIR USE IN THE TREATMENT OF BETA-  
HEMOLYTIC STREPTOCOCCIC INFECTION:  
A PRELIMINARY REPORT

PERRIN H. LONG, M.D.

AND

ELEANOR A. BLISS, Sc.D.

Associate in Medicine and Fellow in Medicine, Respectively, the  
Johns Hopkins University Medical School  
BALTIMORE

The recent observations of numerous European investigators<sup>1</sup> that para-amino-benzene-sulfonamide and certain of its chemical derivatives exert a specific chemotherapeutic effect in beta-hemolytic streptococcic infection are of great interest.

It will be our purpose in this preliminary communication to offer confirmatory observations to certain of the results already obtained by the aforementioned observers and to add new observations regarding the mode of action of these substances.

In the course of our investigations we have used two samples of para-amino-benzene-sulfonamide, one supplied to us by the Jackson Laboratory of E. I. DuPont de Nemours and Company, the other in tablet form under the name of "Prontylin" by the Winthrop Chemical Company. Two derivatives of para-amino-benzene-sulfonamide have also been studied. The first of these, the hydrochloride of 4'-sulfamido-2, 4 diamino-azo-benzene, was labeled "Prontosil tablets," while the second, the disodium salt of 4'-sulfamido-phenyl-2-azo-7-acetyl-amino-1 hydroxy naphthalene-3, 6-disulfonic acid, was sent to us in a liquid state, labeled "Prontosil—2.5 per cent Solution." Both of these preparations

have been supplied to us by the Winthrop Chemical Company. The chemical structure of these products is presented in the structural formulas<sup>2</sup> on the opposite page.

We will not discuss the chemical properties of the substances except to state that in our experience the two preparations of para-amino-benzene-sulfonamide which we have used were soluble in water up to about 0.8 per cent and that, on standing, these substances tended to crystallize slowly out of solution. "Prontosil Solution," on the contrary, was a stable substance. "Prontosil Tablets" were relatively insoluble.

### THE MODE OF ACTION OF PARA-AMINO-BENZENE-SULFONAMIDE AND ITS DERIVATIVES

*In Vitro Experiments.*—We have confirmed the observations of Colebrook and Kenny<sup>2</sup> that dilutions of "Prontosil Solution" had no effect on the growth of beta-hemolytic streptococci in 0.075 per cent dextrose beef-infusion broth or in 50 per cent normal horse serum broth. This is shown in tables 1 and 2. The bacterial growth in the tubes containing "Prontosil Solution" approximately equaled that in the control tubes.

However, when various concentrations of para-amino-benzene-sulfonamide were used a marked reduction in the growth of the streptococci was observed. This occurred not only in the broth cultures but also in the presence of 50 per cent normal horse serum broth. Attempts to test this bacteriostatic action in undiluted horse serum failed because we were unable to secure consistent growths of the organisms in that medium.

It is also interesting to note in this respect that a 1:10,000 concentration of para-amino-benzene-sulfonamide in serum broth markedly inhibited the growth of alpha hemolytic streptococci, gamma streptococci, pneumococcus types I and II, several varieties of Neisseriae from the throat, Micrococcus tetragenus, Haemophilus influenzae and Haemophilus haemolyticus. The growth of Staphylococcus aureus, typhoid bacilli, para A, para B, enteritidis, Flexner, Shiga and several other gram-negative bacilli was not affected by this concentration of the chemical.

It may be of some importance that the chemical seemed to exert a greater bacteriostatic action on one of the strains of hemolytic streptococci than on the other two. This difference between strain Ellis on the one hand and strains C203 and Schw on the other has been observed repeatedly.

From the Department of Medicine, the Johns Hopkins University Medical School.

Read in part before the thirtieth annual meeting of the Southern Medical Association, Baltimore, Nov. 17, 1936.

This investigation has been made possible by a grant from the Chemical Foundation, Inc., 654 Madison Avenue, New York.

The authors are indebted for cooperation to the visiting and house staffs of the various hospitals who have assisted in this investigation.

The mode of action of para-amino-benzene-sulfonamide in a 1:10,000 concentration in 50 per cent horse serum broth was of interest and is shown in the accompanying chart. Growth curves showed that in mediums inoculated with rapidly growing streptococci (twelve hour cultures) the bacterial population at the end of two hours' incubation was the same in the control medium and in the medium containing para-amino-benzene-sulfonamide. However, from this time a marked divergence in multiplication of the cocci occurred and the curve of the normal horse serum broth culture rose rapidly during the first twelve hours, while there was a distinct lag in the presence of para-amino-benzene-sulfonamide. At the end of twenty-four hours the peak of growth had been passed in the normal horse serum broth medium. In the medium containing para-amino-benzene-sulfonamide growth continued slowly through the second twenty-four hours and the curve continued to rise, without, however, touching that of the normal horse serum broth medium. Then growth stopped and the number of viable cocci markedly decreased but not, however, at the rate experienced by the cocci in the normal horse serum broth, thus making the curves meet and cross. This suggested the possibility that a slow multiplication of the cocci was still taking place in the medium containing para-amino-benzene-sulfonamide. Another explanation might be that, in the concentration used, the para-amino-benzene-sulfonamide was bactericidal to a certain degree.

these tests are susceptible to the bactericidal effect of human serum. This phenomenon is of great importance in testing the growth of streptococci in human serum and has but recently been described by Tillett.<sup>3</sup>

The observation, however, that the normal rabbit cannot change "Prontosil Solution" to the active substance has seemed to us to be of great importance because it points toward the possibility that, for the

Growth curve of strain Ellis in normal horse serum broth and in normal horse serum broth containing para-amino-benzene-sulfonamide. Line with solid dots, 50 per cent normal horse serum broth; line with circles, 50 per cent normal horse serum broth + 1:10,000 para-amino-benzene-sulfonamide.

activation of "Prontosil Solution," infection with hemolytic streptococci, or changes brought about by infection, are necessary.

In order to test this hypothesis experimentally we first investigated the effects of high temperature on the activation of "Prontosil Solution" in vivo in the rabbit. Rabbit 271 in the incubator at 37 C. for several hours did not activate the "Prontosil Solution."

Then, following the suggestion of Dr. E. K. Marshall, we tested the effect of administering a strong reducing agent to rabbits previously injected with "Prontosil Solution." It was found that, if 2 Gm. of sodium formaldehyde-sulfoxalate in 20 cc. of distilled water was injected intravenously twenty minutes after 20 cc. of "Prontosil Solution" had been given by the same route, activation of the previously inert serum could be demonstrated. As will be seen in table 3, a definite degree of bacteriostasis was evidenced when streptococci were cultivated in the "Prontosil Solution"—sodium formaldehyde-sulfoxalate serum and that this power persisted to a minor degree over a period of twenty hours. In our experience the serum of rabbits injected with sodium formaldehyde-sulfoxalate alone did not show bacteriostatic serums.

These observations permit the postulation of the hypothesis that reduction is a factor in the activation of "Prontosil Solution." It is known<sup>4</sup> that hemolytic streptococci can, under certain conditions, bring about the reduction of some chemical substances. Certain preliminary observations which we have made suggest that this may explain the activation of "Prontosil Solution" in the presence of hemolytic streptococcic infection.

*In Vivo Experiments.*—There can be little doubt from the observations just recorded that activated "Prontosil Solution" and certain concentrations of para-amino-benzene-sulfonamide exert a distinct bacteriostatic effect in vitro and the assumption is that they act in a similar manner in vivo. However, it seemed to us that the results obtained in the treatment of infected mice (which will be described later) could not be attributed entirely to a bacteriostatic action on the part of these substances.

*In Vitro and in Vivo Experiments.*—Colebrook and Kenny<sup>2</sup> have pointed out that the serum of a patient ill with streptococcic puerperal sepsis becomes increasingly bacteriostatic after multiple doses of "Prontosil Solution." They also noted that the serum of a normal rabbit which had received a large intravenous injection of "Prontosil Solution" did not exhibit bacteriostatic qualities. We have frequently confirmed the second of these observations but have had difficulty in repeating the first. This has been due to the fact that the strains of hemolytic streptococci which we have employed in

We therefore studied the exudate obtained by peritoneal puncture from mice which had been infected nine hours prior to the first puncture and treatment. In table 4 the results of these observations can be seen. In the experiment here outlined, para-amino-benzene-sulfonamide was used as the therapeutic agent. Similar results have been obtained when "Prontosil Solution"

was employed. It is evident that phagocytosis of the streptococci by the polymorphonuclear leukocytes plays a paramount rôle in controlling the infection in the early stages of treatment and that later the monocytes join in this phenomenon. The following should be noted in respect to these experiments. Levaditi and Vaisman<sup>2</sup> believed that capsular production by streptococci was interfered with in the presence of these therapeutic agents. We were unable to confirm this observation.

We have noted already that, in vitro, the multiplication of streptococci was inhibited by para-amino-benzene-sulfonamide. It is possible that this may also occur in vivo, but in addition to this effect of the chemical we feel that the streptococci must also be damaged to permit such a marked degree of phagocytosis by the leukocytes. Thus, there is evidence that para-amino-benzene-sulfonamide and "Prontosil Solution" both inhibit the growth and injure hemolytic streptococci in the animal organism.

CURATIVE EFFECT OF "PRONTOSIL SOLUTION" AND PARA-AMINO-BENZENE-SULFONAMIDE IN EXPERIMENTAL BETA-HEMOLYTIC STREPTOCOCCIC INFECTIONS IN MICE

Our experience has been that a single prophylactic dose of 1 cc. of "Prontosil Solution" administered to mice, subcutaneously, twenty-four hours prior to infection by the intraperitoneal injection of from 100 to

1,000 minimum lethal doses of the strains C203, S24 or Schw was ineffective in protecting the mice against infection. While the survival time of the treated mice was longer than that of the untreated controls, no striking results were obtained. This result was to be expected because of the rapidity with which the "Prontosil Solution" was excreted in the urine.

In contradistinction to the prophylactic effects of "Prontosil Solution" the therapeutic effects of this substance were remarkable.

As noted in table 5, four different types of beta-hemolytic streptococci have been used in the therapeutic experiments. All the strains employed were at maximal mouse virulence; i. e., from 10<sup>-8</sup> to 10<sup>-9</sup> cc. of a twelve to fourteen hour blood broth culture regularly killed mice within forty-eight hours. It has been our experience with these strains during the past year that never has a mouse survived an intraperitoneal injection of

10<sup>-6</sup> cc. of such a culture. This observation covered several hundred mice. Hence we feel reasonably certain that our results in this respect are completely valid. It is also of interest to note that with four exceptions all the 102 treated mice had positive blood cultures twelve hours after intraperitoneal inoculation.

In the preliminary experiments, the immediate survival rate in the treated mice was excellent. But, as can be seen, after the treatment was discontinued the mice began to die, some in the first few days, others as late as thirty days after the therapy had been discon-

2. Levaditi, C., and Vaisman, A.: *Compt. rend. Acad. d. sc.* **200**: 1014 (May 13) 1935; *Compt. rend. Soc. de Biol.* **119**: 946, 1935

tinued. In this respect our results differed from those reported by Colebrook and Kenny and others.<sup>6</sup> Because of an interval of generally twelve hours between the second and third treatments, we decided to infect two large groups of mice, one with strain C203, the other with strain Schw, and to treat them at four hour intervals for a period of sixty hours after the commencement of the therapy. By doing so we hoped to approach the treatment schedule which is followed in severe human cases. Then after this intensive period

tions in mice, the results seemed to be a little better than those obtained with "Prontosil Solution." The immediate survival rate was definitely augmented and more mice have survived over a period of thirty days. These observations are in harmony with those described by several European investigators.<sup>7</sup> The explanation of these late deaths after therapy has been discontinued can be made clear. One must remember that the white mouse lacks any natural resistance to intraperitoneal infection with multiple

+ Died of beta-hemolytic streptococci infection.  
0 Died of another infection (mostly mouse typhoid).

of early treatment we planned to taper off the therapy gradually over a two weeks period. This plan seemed to work very well in practice, because in the C203 group of treated mice there were but six deaths and in the Schw group seven deaths from streptococci infection during the first two weeks. However, after the cessation of treatment, deaths from streptococci infection appeared in both groups, although to a lesser degree than in the first groups of treated mice. When solutions of para-amino-benzene-sulfonamide were used in the treatment of these experimental infec-

lethal doses of a strain of hemolytic streptococcus of maximal virulence. It always dies. Neither is it easy to immunize these mice against these same virulent strains. We have tried repeatedly to immunize mice with C203 and Schw vaccines without obtaining a degree of immunity capable of offering resistance to 100 lethal doses of the homologous strains. With these facts in mind, one can understand why the mice die after treatment has ceased. Unless the infecting agent has been completely eradicated, the mouse will probably succumb.

We have obtained results similar to those reported by Colebrook and Kenny and others<sup>7</sup> when we attempted to treat experimental mouse infections produced by hemolytic streptococci of low mouse virulence. We could prolong the survival period of the treated mice over that of the untreated mice but were unable to influence the final mortality rate in the treated animals.

we have attempted to evaluate its curative effects in patients ill with beta-hemolytic streptococcic infections.

It is always necessary in testing new therapeutic agents to adopt a skeptical attitude toward the results obtained. Too often have early brilliant therapeutic successes eventually proved to be due to chance or to optimism of the reporter. Bearing this in mind, it is

14	Ludwig's angina	♂ 70	8	.....	3.25	.....	3.25	1	Died 22 hours after first parenteral injection
15	Cellulitis of legs; septicemia	♂ 57	7	Blood culture 640 colonies of B.H.S. per cc. of blood	2.5	.....	2.5	1	Died 9 hours after first parenteral injection
16	Acute bilateral oti- tis media and mac- toiditis; septicemia	♂ 5	24	Blood culture 2,150 colonies of B.H.S. per cc. of blood	11.75	.....	11.75	13	Gravely ill; possible right jugular thrombosis; meningismus; developed metastatic infections in both elbows and over right clavicle; blood culture negative on 5th day; hemoglobin fell to 40%; 3 transfusions after negative blood culture; sterile pleural effusion eleventh day; temperature normal 18th day discharged 26th day
17	Scarlet fever; cer- vical adenitis	♀ 6	9	Blood and cere- brospinal fluid negative	5.25	.....	5.25	4	Marked meningismus with 400 cells in C.S.F.; glands decreased rapidly; temperature fell to normal in 6 days
18	Scarlet fever; cer- vical adenitis; bi- lateral otitis media	♀ 6	18	.....	....	5.4 Pront- osil	5.4	3	Septic type of temperature up to 104; multiple myringotomies both ears with abundant purulent discharge; temperature fell to normal in 24 hours; ears clear in 3 days
19	Acute follicular tonsillitis; right peritonsillar abscess	♂ 22	6	B.H.S.	2.5	7.2 Pront- osil	9.7	4	Marked decrease in swelling and edema within 40 hrs.; temperature normal in 40 hrs.; abscess ruptured (?) at 27 hrs.; patient discharged 5 days after admission

\* Seven other patients have been treated with para-amino-benzene-sulfonamide and its derivatives since this table was prepared.

#### THE CLINICAL USE OF "PRONTOSIL SOLUTION," "PRONTOSIL TABLETS" AND PARA-AMINO- BENZENE-SULFONAMIDE

In view of the very definite therapeutic effect of para-amino-benzene-sulfonamide and its derivatives on experimental hemolytic streptococcic infection in mice and because of the encouraging reports of their use by European clinicians in human streptococcic infections,

possible that the good clinical results observed by us after administration of para-aminobenzene-sulfonamide and its derivatives were due to chance; but it is not possible that the results in treatment of experimental infections were. Therefore we believe that continued clinical observations of the effect of these substances in the treatment of hemolytic streptococcic infections in human beings should be vigorously prosecuted.

## TOXIC EFFECTS

In the course of observations on the patients presented in this report we have noted that the therapeutic agents employed are relatively nontoxic. The intravenous injection of "Prontosil Solution" frequently resulted in nausea, vomiting and an immediate bowel movement. As we have found that following a subcutaneous injection of "Prontosil Solution" the substance appears in the urine in fifteen minutes, we are of the opinion that the intravenous use of the product is unnecessary. We have not observed any changes in the urine, white blood cell count or red blood cell count that could be attributed to the therapeutic agent. None of our patients developed sulfemoglobinemia. We have been insistent that no saline laxative be used while a patient is under treatment. The only known toxic manifestation was that of fever. When a large dose (100 cc.) of "Prontosil Solution" was administered under the skin in a normal human being the temperature mounted to from 102 to 103 F. (rectal) in from eight to twelve hours. This fever lasted twelve hours and then the temperature declined rapidly to normal. A feeling of lassitude and slight frontal headache was experienced by the subject during the febrile period. This reaction was not observed in patients who received smaller divided doses of "Prontosil Solution" but has been observed in those who received a single large dose. No toxic symptoms were observed in mice that had received large amounts of "Prontosil Solution" over a long period of time.

The samples of para-amino-benzene-sulfonamide that we tested were definitely toxic for mice. A subcutaneous injection of 9 mg., repeated after a three hour interval, produced in the animals symptoms of a bilateral vestibular dysfunction and a curious spastic paralysis. However, within four hours these symptoms disappeared and the mice appeared as healthy as ever. In patients, long continued therapy with this substance did not result in toxic manifestations.

## DOSAGE

When "Prontosil Solution" is used, we feel that it is important to administer a large amount during the first twenty-four hours of treatment. Hence we have adopted the following measure for determining total dosage during the first twenty-four hours of treatment: For each pound of body weight up to 100 pounds (45 Kg.) we advise 1 cc. of the substance. Between 100 and 150 pounds (68 Kg.) the total first day dose is 100 cc. For patients weighing over 150 pounds the dose is determined on the basis of 0.75 cc. per pound (450 Gm.) of body weight. After the first twenty-four hours the total daily dose should be about one half of the amount administered in the first twenty-four hours except in patients suffering from beta-hemolytic streptococcic septicemia. In these individuals the original amount should be continued until the blood stream is sterile.

As it has been shown that para-amino-benzene-sulfonamide in a concentration of 1:10,000 is bacteriostatic in vitro, we have tried to attain a high concentration in the patients treated with this substance. We know little about the absorption and nothing about the excretion of this drug. However, we have found that some patients will tolerate a gram of para-amino-benzene-sulfonamide for each 20 pounds (9 Kg.) of body weight per day for at least one month.

When para-amino-benzene-sulfonamide is used orally in conjunction with "Prontosil Solution" parenterally,

one should decrease the estimated parenteral dose by 20 cc. for every gram of para-amino-benzene-sulfonamide administered. When one is administering either "Prontosil Solution" or para-amino-benzene-sulfonamide to patients, the total calculated daily dose should be divided into four parts and given at intervals of six hours.

Finally, it should be remembered that saline laxatives and cathartics should not be administered during the period in which these substances are being used as therapeutic agents.

## SUMMARY AND CONCLUSIONS

In view of the experimental evidence presented, we believe that the careful clinical use of para-amino-benzene-sulfonamide and its derivatives in the treatment of human beings ill with infections due to beta-hemolytic streptococci is warranted.

## CARCINOMA OF THE RECTUM

## FACTORS AFFECTING ITS CURE

G. V. BRINDLEY, M.D.

TEMPLE, TEXAS

Several facts pertain to cancer of the rectum which favorably influence the prognosis. A more optimistic view with regard to malignant conditions here should prevail. Practically all patients with carcinoma of the rectum can be cured when adequate surgery is instituted in the early stages of the disease. Rectal cancers can be diagnosed easily and with certainty while the lesion is early and curable. This ideal falls far short of attainment. Lahey<sup>1</sup> believes that one patient in four with this condition can be relieved by surgery. Miles<sup>2</sup> reports 21 per cent of five-year cures for all cases seen presenting a rectal malignant growth. Fansler<sup>3</sup> writes that not more than 40 or 50 per cent of those patients are suitable for radical operation. Dixon,<sup>4</sup> reviewing a large series at the Mayo Clinic, states that in more than 50 per cent of the cases the growths were inoperable. Bowing and Fricke,<sup>5</sup> analyzing the end results of the treatment of 500 patients by the combined measures of surgery and radiation therapy, report 22.53 per cent of five year good results. Many facts concerning this disease make it possible for a larger percentage of patients with a rectal malignant condition to obtain relief. A discussion, therefore, of some of the factors that modify the probability of cure of the patient with carcinoma of the rectum seems timely. The records at the Scott and White Clinic of 167 patients having cancers of the rectum have been reviewed, and the study forms the basis for the conclusions in this presentation.

The extent of the neoplasm is the most important modifying factor. Cancer of the rectum, early, as

cancer elsewhere in the body, is a local lesion and while in this stage of development is readily amenable to surgical removal, with the probability of permanent relief. The carcinoma begins in the mucous membrane from the crypts or glands of Lieberkühn as a node of proliferating, abnormal epithelium. It arises frequently from an adenoma or a papilloma, and according to Rosser<sup>6</sup> sometimes from an ulcer, a fissure or a fistula or from leukoplakia.

How long does a rectal cancer remain a local lesion? Its first method of spread is by continuity of tissue as the growth develops. The next is by metastasis through the lymphatics, and occasionally the cancer cells are disseminated by the blood stream. Lymphatic invasion and distant venous metastasis seldom take place before the muscular coats of the intestine have become deeply invaded or until after the lesion has grown entirely through its wall. Certainly the more deeply the lesion has penetrated into the intestinal wall, the greater the probability of metastasis. Gordon-Watson<sup>7</sup> writes: "It is probable that the state of lymphatic invasion is seldom reached under six months and usually takes longer." Miles states, "Direct extension through the muscular coat of the bowel appears to be a slow process and the fascia propria of the rectum is not usually invaded until the disease has existed for eighteen months." Wilkie<sup>8</sup> believes that cancer of the rectum remains a local disease probably at least a year.

It is impossible to ascertain the exact time at which a cancer of the intestine begins. Probably most of the growths have existed a few months before suggestive signs and symptoms were in evidence. Most lesions, therefore, are of a definitely longer duration than the patient's history would seem to indicate. In this study I found the average duration of symptoms for the patient with an operable malignant growth to be 9.4 months. One patient of the operable group gave a history dating back twenty-four months. The average duration of symptoms of those cases considered inoperable when first examined was fourteen months. Rankin<sup>9</sup> finds in the average case of rectal carcinoma that symptoms have been present about eleven months. Since the extent of the lesion is an important factor affecting the cure, it is an encouraging fact to know that for a majority of patients the cancers are local, removable and curable for many months.

The time at which the diagnosis is made is a vital factor, for it determines the extent of the carcinoma. This is also the one factor about which most can be done toward increasing the number of cures. Therefore an endeavor should be made to diagnose more early lesions. The symptoms and signs of early disease should be remembered. Blood in the stool is the most important first indication of cancer, and a mild rectal discomfort is next. The patient describes this as an uneasiness, a heaviness, a weighty feeling, a soreness or a mild cramping. Intense pain is practically never an early manifestation of this disease. A history of bleeding was given by 80 per cent of these patients, and the complaint of a rectal discomfort was made by 68 per cent. A change in bowel habit may be the

earliest symptom. These few signs and symptoms are sufficient to cause rectal cancer to be suspected, and, when suspected, a careful digital and proctoscopic examination should be made. Practically all rectal cancers can be diagnosed by these two simple procedures. Wheeler<sup>10</sup> states that 90 per cent of rectosigmoidal and rectal cancers can be diagnosed by digital palpation. Bargaen<sup>11</sup> writes that about 95 per cent of all rectal lesions are within reach of the examining finger and concludes that delay by the physician in making a digital examination is one of the chief factors contributing to the poor prognosis of carcinoma of the rectum. Certainly if digital and proctoscopic examinations with biopsy were done always on patients with such complaints, more early diagnoses would be made and the resulting number of cures for patients with rectal carcinoma would be materially increased. Lockhart-Mummery<sup>12</sup> states that more than 75 per cent of cures can be expected when the diagnosis is made early. Abel's<sup>13</sup> statistics show that 77 per cent of patients are free from recurrence five years after surgical extirpation when the operation is performed early before the glands become involved.

The size of the lesion is to be taken into consideration, since it is somewhat of an index to the duration of the disease. Cutting<sup>14</sup> stated that a carcinoma which has encircled three fourths of the intestine is of about one year's duration, while Miles believes that it probably requires eighteen months for a tumor to reach such an extent. The size of the neoplasm, however, is a poor index of its curability. Frequently the prognosis is more hopeful for the case presenting a large tumor than for the one presenting a smaller neoplasm. Pfeiffer<sup>15</sup> states that the size of the growth bears no necessary relation to metastasis; in fact, the relation is more likely to be inverse. McVay<sup>16</sup> also finds the tumors without glandular involvement to be about average in size. Several patients of our series with tumors 7 or 8 cm. in diameter have remained well after surgical extirpation, while, in contrast, others with cancers only 3 or 4 cm. in size have developed a recurrence following their operation. The explanation for the end results in these cases is to be found in the degree of activity of the malignant cell and in the different clinical varieties of rectal cancer. Three different kinds are seen: the papilliferous, the adenoid and the colloid. The papilliferous grows rapidly on the surface and may involve the entire circumference of the intestine and protrude into and fill its lumen, producing a very large tumor before there is deep invasion of the muscular coats by malignant cells. Therefore the papilliferous, fungating, protuberant neoplasm, growing chiefly into the intestinal lumen, metastasizes slowly and, even though a very large tumor has developed, is still a favorable lesion for removal; on the other hand, the ulcerating cancer of the adenoid or colloid variety which has penetrated deeply into the rectal wall, even though small, is frequently highly

malignant, may metastasize early, and often tends to recur after wide removal. The size of the tumor, therefore, is a poor index to its curability.

The pathology of rectal neoplasms is quite an important factor influencing the probability of cure. A specimen for biopsy can be obtained readily when the proctoscopic examination is being done. By this procedure the diagnosis usually can be definitely confirmed and the degree of malignancy ascertained. Occasionally the biopsy does not show the correct grade of cell activity and may fail even to demonstrate the presence of cancer. This probably is due to the fact that the section failed to include any of the actual tumor, or to changes in the tissue produced by degeneration and infection. A negative report, therefore, does not exclude carcinoma. Specimens have been obtained for pathologic study from 124 patients. Twenty-six of these were of the papillary variety, four were of the colloid variety, ninety-one were adenocarcinoma (simplex) and three were squamous cell epitheliomas.

A study of the degree of malignancy, based on cell differentiation as advocated by Broders, was made, and it was found that nine carcinomas were grade 1, fifty-five were grade 2, forty-eight were grade 3 and five were grade 4. The character of specimens obtained from seven lesions did not permit of grading. Sixty-four of the 117 cancers graded, or 54.7 per cent, were found to be either grade 1 or grade 2 in degree of malignancy. Bowing and Fricke report 70 per cent are in the grade 1 and grade 2 groups. Hayden and Shedden,<sup>17</sup> with a somewhat different method of grading, state that 77 per cent of rectal cancers are in the lower grades of malignancy. These neoplasms of grades 1 and 2 are slow to metastasize and, by wide surgical removal of such lesions, a high probability of cure may be expected. It is a fortunate fact, favorably influencing prognosis, that a definite majority of rectal carcinomas have a low degree of activity of the malignant cell.

Seventy of the seventy-six specimens obtained by removal of the growth permitted examination with reference to the depth of penetration of the intestinal wall by cancer and also with regard to the frequency of demonstrable glandular metastasis. The lesion was found superficial to the muscle in twenty-one specimens. The muscles were invaded by carcinoma cells in ten, and in forty-seven the cancer had penetrated through the intestinal wall to or beyond the serosa. That is, the carcinoma had invaded into or through the muscular coats in fifty-two of the seventy-three cases, or 71.2 per cent. The depth of penetration of the carcinoma into or through the intestinal wall definitely affects the probability of glandular metastasis and therefore the likelihood of cure. Dukes<sup>18</sup> states that as a rule lymphatic dissemination does not play any part in the spread of cancer of the rectum until the growth has penetrated by direct continuity into the perirectal tissues.

Glandular metastasis was demonstrated in only sixteen of the seventy specimens, or 23 per cent. Jones and McKittrick<sup>19</sup> found glandular metastasis in only 32 per cent. MacCarty<sup>20</sup> made a study of 1,826 rectal and sigmoidal carcinomas and reported glandular

involvement in 38 per cent. Dukes made a study of 100 cases and reported glandular involvement in forty. McVay, in a very detailed examination of 100 resected rectums, demonstrated metastasis to the glands in forty-seven. Such statistics indicate that rectal carcinoma is slow to metastasize to lymph glands and that for a majority of the patients the cancer remains local until late. Glandular metastasis markedly affects the curability. Rankin and Broders<sup>21</sup> report only 20.68 per cent of good results when the glands were involved and 57.87 per cent of good results when the glands were free.

The degree of malignancy should be considered in selecting the type of operation to be performed. Sometimes the grade of the cancer will be the determining factor in deciding operability. Certainly all definitely extirpable carcinomas of the rectum should be treated surgically. Surgery, however, should be advised more often for the more advanced or borderline lesions of the lower grades than would be considered for the higher degrees of malignancy of the same extent. Neoplasms of a highly malignant degree and of the borderline operability are treated preferably by radium and roentgen rays rather than by surgery. Radiation therapy is indicated for many of the extensive anal epitheliomas. However, a posterior hot-knife excision of the rectum is the preferable treatment for all operable squamous cell lesions of this location. A knowledge of pathology, therefore, is an invaluable aid in determining the preferable method of treatment. There are also four factors related to pathology which materially affect the prognosis. They are the different clinical varieties of cancer, the degree of activity in the carcinoma cell, the depth of penetration of the intestinal wall by malignant tissues and the presence or absence of glandular involvement.

The mobility of the growth is a very important factor influencing the treatment. All movable lesions are extirpable, and proper surgical excision offers to such patients the most for a favorable prognosis. Restriction in the mobility of the neoplasm decreases the operability, increases the hazard of surgical treatment and diminishes the probability of permanent relief. However, when a lesion is fixed it is important to remember that the fixation may be due to accompanying inflammatory changes rather than to an extension of the disease. The enlargement of the regional lymph glands is due frequently to a simple adenitis rather than to a metastatic malignant growth. Sometimes after a colostomy, by putting at rest the diseased intestine and by local treatments, the inflammatory changes subside and a cancer that apparently was fixed and inoperable becomes mobile and removable. Gordon-Watson also reports that some immobile neoplasms will be converted into operable tumors by radiation therapy.

The sex of the patient has a bearing on the cure to a slight degree. The prevalence of rectal cancer is

Location of the 167 carcinomas reviewed in this study.

higher in the male. Buie<sup>22</sup> finds that 64 per cent are of the male sex. Pfeiffer states that the ratio is almost that of two to one. There were ninety-five males and seventy-two females in this group which was reviewed. That is, 57 per cent were males and 43 per cent were females. The pathology is not influenced, apparently, by the sex. Owing to the narrower male pelvis, surgical removal of a rectal neoplasm for him is more difficult and the pelvic peritoneum of the man is less resistant to infection than is that of the woman. Because of these facts, surgical extirpation of the rectum carries a higher mortality for the male. Sir George Newman<sup>23</sup> reports that the prospects of survival are better for women than for men after radical operation. Yeomans<sup>24</sup> states that the mortality is 7 per cent greater for men.

The age of the patient definitely affects the prognosis. The youngest patient in this group was 23; the oldest was 84. There were five patients in the third decade of life, sixteen in the fourth, thirty-three in the fifth, forty-five in the sixth, thirty-nine in the seventh, twenty-six in the eighth and three in the ninth. The tissues of the young are more elastic and have a richer blood supply, and their lymphatics are more open, factors that are favorable to the rapid growth and dissemination of a neoplasm, while the fibrotic, sclerosing changes accompanying senescence tend to retard the development and spread of a malignant condition. Therefore, in the young the lesion is usually of a high grade malignancy and of a more rapid growth and metastasizes early. Pathologic specimens were obtained from sixteen patients under 40 years of age. A study of these showed two to be grade 1, four to be grade 2, eight to be grade 3 and two to be grade 4. That is, practically two thirds of the patients under 40 had highly malignant tumors. When the neoplasm in the young is operable, it should be removed together with all lymph bearing tissue after the most thorough manner. Three patients under 40 were operated on now more than five years ago. Two of these are alive now, one eight years and one five years after the malignant growth was removed. Lockhart-Mummery writes: "I have no record of any patients under 30 who has not died from prompt recurrence." Meckling<sup>25</sup> states that a patient under 30 years of age does not recover from rectal cancer. Unquestionably the prognosis is grave for the young patient with carcinoma of the rectum.

The physical condition of the patient modifies the treatment and prognosis. All surgery is precluded for some on account of their age, and for others because of disease of either the heart, kidneys or lungs or some other debilitating illness; and only a restricted operation should be advised for some others, because of the hazard of a more radical surgical procedure. It is seldom necessary, however, that the benefits offered by surgical treatment be denied a patient with cancer of the rectum because of his physical status. A great deal can be done to rehabilitate the poor risk. Rest, foods, fluids, dextrose, blood transfusions and encouragement will do much to prepare such patients for an operation. There were four patients over 70 years of age for whom a radical removal of the rectum was performed and two others for whom a wide local excision of the lesion was done, and all had a satisfactory convalescence.

The mental attitude of the patient can be an important factor. Some are not willing to accept a colostomy, even though it would permit a safer and wider removal of their disease. For such patients the surgeon should be willing to give due consideration to other therapeutic measures or to other surgical procedures that will permit either the restoration of intestinal continuity or the making of a posterior anus. Some patients assume that their condition is hopeless and are unwilling to make the effort to get well. This is true of a few even after they have accepted surgery. There were twenty-two of this series who declined the aid offered by surgery. Radiation therapy offers the most to the patients who assume such an attitude.

The location of the lesion must be given consideration, for the pathologic types vary in the different parts of the intestine and the symptoms are modified by the portion that is involved. The smallest caliber of the large intestine is in the rectosigmoid. The cancer often grows along the blood and lymph vessels around the inside of the intestinal wall, producing annular, constricting tumors. The small caliber of the bowel and the nature and development of the neoplasms here fortunately tend to a rather early manifestation of symptoms. Owing to these facts, naturally, the first symptoms of a rectosigmoidal cancer are frequently those indicative of a partial obstruction. Sometimes patients with malignant growths in this region first consult a physician because of an acute obstruction. Neoplasms of the rectal ampulla, owing to the large size of the lumen, rarely cause marked obstruction and then only after the lesion is far advanced. Cellular, fungoid growths which are prone to early ulceration and bleeding are the type of tumors often seen here and in the lower part of the rectum. Blood and mucus in the stools are the usual first signs of a malignant condition of this part. Cancers of the anus are usually epitheliomas. They early become fissured, ulcerated and infected. Because of this and the resulting spasm and contraction of the sphincter muscles, a discomfort or even pain is frequently and early a manifestation of neoplasms of this location. The position of the carcinoma will also have a direct bearing on its accessibility and therefore the type of operation to be performed and the hazard of its removal. So the location of the lesion has a definite relation to the pathologic condition, the symptoms, the treatment and the prognosis.

Improper first treatment is a definite factor affecting the cure of rectal cancer. Many patients are treated for hemorrhoids, some being given ointments even without an examination. Occasionally the patient is treated for colitis. Sometimes an injection is made into a malignant lesion, and for others a local cauterization is done. A review of the records of these 167 cases referable to the nature of recent treatments before admission to the hospital shows that fifteen patients had a hemorrhoidectomy performed, nine were given injections for hemorrhoids, five had a local cauterization of the lesion, ten other patients had some other type of surgical work, and twenty-seven had some kind of medical treatment. It is seen by this review that sixty-six patients, or approximately 40 per cent, had some type of inadequate therapy before their conditions were definitely diagnosed. Most patients, previously subjected to either injections or local cauterization before having wide removal of the neoplasm performed, have not remained well. Incomplete operations unquestionably do harm by tending to disseminate the disease and by preventing the patient from coming earlier for proper treatment.

The attitude of some physicians occasionally is discouraging. They assume that treatment is of no avail and therefore that all cases of rectal cancer are hopeless. While it is true that many of these patients come to the physician with lesions so advanced as to be irremovable, there are, on the other hand, more than 50 per cent of the patients for whom the growth can be removed with a definite prolongation of life for some, and for many others a permanent cure. As stated previously, twenty-two patients declined surgery and of the 145 remaining patients of this series the cancerous intestine was removed for seventy-six, or 52.4 per cent.

If the twenty-two patients declining had accepted surgery, the percentage of operability would have been materially increased.

The type and thoroughness of the operation performed are two of the most important factors influencing the curability of this disease. The combined abdominoperineal excision is the anatomically correct and classic operation; but to adopt it as a routine method has not seemed wise. Rankin<sup>26</sup> writes that he has found the operation as advocated by Miles not to be applicable for more than 20 per cent of these cases. Reporting on another group of patients, he states that less than one third were considered suitable for this type of excision. Wilkie states that the Miles operation presents difficulties and risks that are serious and unjustifiable in approximately 50 per cent of the cases. The combined operation certainly entails a greater surgical hazard. Dixon believes that the average mortality for the combined procedure is about 12 per cent and reports only 4 per cent for the posterior excision. Unquestionably rectal neoplasms should not and cannot all be operated on by the same surgical plan. A graded operation, with the procedure divided into two or more stages, is usually preferable, doing much to lower the surgical mortality. Occasionally a rectosigmoidal lesion can be removed by an abdominal approach. A majority of lesions in the rectosigmoid and upper part of the rectum, however, should have a combined abdominoperineal excision, usually in two stages. Some neoplasms of the ampulla are preferably removed by the combined method, but for a majority of tumors of the ampulla and for most cancers of the lower part of the rectum and anus a posterior hot-knife excision, following a preliminary colostomy, seems preferable.

Radiation therapy deserves proper consideration. Five year cures by this method of treatment have been reported by several, among whom are Bowing, Binkley<sup>27</sup> and Gordon-Watson. While my experience has been

limited, I would reserve this therapy primarily for the treatment of the patients with inoperable neoplasms, for those whose physical status will not permit surgery, for the patients who refuse to accept surgical treatment, for grade 4 malignant growths, for the extensive anal epitheliomas and as an adjunct to surgery. Practically all patients treated surgically were given either pre-operative or postoperative irradiation, and some were given both.

The instrument used by the surgeon for the excision may be a definite factor affecting the end result. The use of the hot-knife for the removal of a cancerous rectum has much to commend it. The hot-knife is a sharp, platinum, loop cautery tip, heated electrically. The advantage gained by the general adoption of the hot-knife for the excision of carcinomatous tissue has been stressed repeatedly by my senior associate, A. C. Scott.<sup>28</sup> My further experience with the cautery confirms conclusions published in a previous paper.<sup>29</sup> I find that the difficulty of the excision is not augmented by the use of the cautery knife. A line of cleavage is more readily obtained by it and therefore a more accurate dissection can be made. Larger and more advanced growths can be removed with the hot-knife, thereby extending the field of operability. The lymphatics are sealed when severed, and therefore there is less likelihood of dissemination of the cancer cells. There is diminished absorption of toxic substances from the wound, since the lymphatics are sealed. The loss of blood is less, for the hot-knife tends to close the capillary and small blood vessels. The postoperative pain is decreased. Because of these facts, the frequency and degree of shock are lessened and recurrence is definitely diminished.

In our clinic we have performed forty-eight consecutive posterior hot-knife excisions of malignant rectums with only one operative death, or a mortality of approximately 2 per cent. This fact would seem to justify the statement that it is a safer procedure than the usual knife excision. A surgical removal of the cancerous rectum by some method was performed for seventy-six patients. There were two other hospital deaths, or an

operative mortality for the entire surgical group of 3.9 per cent. The fact, which is substantiated by these statistics, that the surgical extirpation of a malignant rectum is a relatively safe procedure with a low mortality should be emphasized, in the hope thereby that patients will earlier and more readily accept treatment.

A detailed study has been made of fifty resected rectal carcinomas from patients operated on more than three years ago. The accompanying tables give an analysis of the work. Forty-eight patients were operated on five years or more ago. There were two hospital deaths, and two cases have not been traced.

26. Rankin, F. W.: Two Stage Resection for Carcinoma of the Rectosigmoid and Rectum, Surg., Gynec. & Obst. 53: 670 (Nov.) 1931; A Survey of the Treatment of Carcinoma of the Rectum and Rectosigmoid, Interstate Postgraduate Assembly, North America, October 1932.

29. Brindley, G. V.: Cancer of the Rectum, Study of One Hundred Case Records, South. M. J. 25: 441-448 (May) 1932.

Twenty-two patients, or 50 per cent, of the remaining forty-four obtained from five to fourteen years of good end results from surgical treatment. Thirty-three of these forty-eight patients were operated on by the method of posterior cautery excision after a preliminary colostomy had been performed. The two untraced patients were in this group and two other patients are known to have died from some cause other than a recurrence of the malignant condition. Of the remaining twenty-nine, fourteen, or 48 per cent, obtained five years or more of good end results. Therefore the ultimate results obtained by a posterior hot-knife excision further commend its adoption for the extirpation of a rectal cancer.

## CONCLUSIONS

Carcinoma of the rectum is a curable disease. Many factors influence the treatment and prognosis of the patient with a cancer of the rectum, making it wise to study and treat each case individually. Among these factors are to be considered the location, the size and the extent of the lesion, the mobility of the growth, the pathology of the neoplasm, the sex, age, physical state and attitude of the patient, the availability of radium and roentgen therapy, proper preoperative and post-operative care of the patient, and the instrument used for the excision of the malignant intestine. The salient facts to be remembered are that cancer of the rectum is a local lesion for a few months; that the spread of carcinoma here tends to be slow; that the first symptoms are a change in the frequency and character of stool; that the diagnosis can be made easily, early, with certainty by simple measures; that the rectum is not a vital organ; that a colostomy is not particularly disabling; that the surgical removal of a malignant rectum is a relatively safe procedure, and that wide, hot-knife excision of early lesions gives a high percentage of permanent cures.

## ABSTRACT OF DISCUSSION

DR. CURTICE ROSSER, Dallas, Texas: A few years ago biopsy enjoyed an entirely undeserved oblivion. Partly because it has been found that "examination-massage" of a malignant tumor is probably as dangerous as or even more dangerous than the careful removal of a section of that tumor, and partly because of the perfection of instruments for biopsy, including the use of the coagulating current, biopsy is now a more or less standard procedure. In spite of the fact that a great many more physicians are now equipped by experience to recognize a typical malignant growth of the rectum by inspection and palpation, there continues to be a need for microscopic tissue examination. The statistics of Dr. Brindley have shown that a person with a grade 4 malignant growth of the large bowel will probably die of cancer eventually, regardless of what is done about it, and a biopsy in that instance might change one's plan of attack on the growth. At the other extreme, a person with a grade 1 cancer may survive after even a simple local removal; consequently, the advance information afforded by biopsy has definite value here. Frank recognition of the etiologic significance of benign lesions of the rectum and anus in relation to rectal cancer will do a great deal to advance the time at which a definite diagnosis can be made. That adenoma of the rectum is a direct etiologic factor is now generally conceded. I reported before this section in 1930 a group of cases of long standing, inflammatory and irritative lesions of the anal canal, such as hemorrhoids, fistulas and anal ulcers in which there was definite evidence that the benign lesions had an etiologic significance in connection with the malignant growth that was discovered superimposed. A mixed tumor of this type—an implanted malignant growth on the basis of an adenoma or an old inflammatory lesion of the anal canal—frequently fails to give a clear-cut picture on examination through the proctoscope. A biopsy is therefore advisable when the suspicion of malignancy is aroused. Accurate and comprehensive diagnostic measures are essential in the presence or possibility of any rectal neoplasm. The entirely laudable attempt to popularize rectal examinations on the part of the practitioner has at the same time deeply inculcated the idea that this procedure may properly consist entirely of the casual introduction of the index finger. The fact that the majority of rectal tumors in their curable stages are in the upper rectal zones suggests that careful direct visualization of the entire rectum and rectosigmoid is likewise indicated. The fortunate trend of opinion that has rescued biopsy from its previous disfavor affords an additional safeguard to the patient when the presence of a malignant condition or the degree of malignancy is undetermined.

DR. FRED W. RANKIN, Lexington, Ky.: I disagree with Dr. Brindley on one point. I have the firm conviction that the most important factor influencing prognosis is the activity of the cancer cell as graded by Broders' classification of malignancy, and I believe firmly that these other factors of duration of growth, glandular metastasis and the extension of the malignant process through the muscularis of the bowel and into the regional lymphatics, and beyond, are in direct ratio to this activity. Broders has shown very clearly just what Dr. Brindley's experience has been here, that the cancer of the rectum has a tendency to occur most often in the lower grades, 1 and 2. My figures were 65 per cent in the grade 1 and grade 2, and I think that this accounts in large measure for the hopeful prognosis following the successful extirpation of cancers in this region. Let me also emphasize the fact that in resected specimens of cancer of the rectum 46 per cent show glandular involvement. I believe that when possible radical surgery should be applied after the principles of Halstead not only to the breast, the lip, the tongue and the stomach, but also to cancers of the rectum. I heartily agree with Miles's statement that it is just as important to remove the mesentery of the sigmoid in doing a radical operation for cancer of the rectum as it is to remove the glands of the axilla in doing an operation for cancer of the breast. Within the last three years I have found myself changing more and more from the graded procedure of my own, which is a modification of Miles's operation, and somewhat similar to Lahey's modification, brought out in 1929, to the one-stage operation of Miles. In a high percentage of cases, however, debilitated and desiccated individuals are seen too late to apply this radical procedure in a

routine manner and for that reason it is necessary to resort to the less radical procedure of colostomy and posterior resection. In the last fifty cases I did eighteen one-stage operations, sixteen colostomies and posterior resections, and four of my own type of operations. In that group of resections, one patient died following resection and colostomy and eighteen survived radical one-stage operations but I don't think that is a fair way to estimate operative mortality, for, in the whole fifty, actually five patients died, four of them following colostomy alone.

DR. G. V. BRINDLEY, Temple, Texas: I wish to express appreciation to Dr. Rosser and Dr. Rankin for the manner in which they amplified the paper in their discussions. Unquestionably rectal neoplasms should not all be operated on by the same surgical plan. It was shown on the screen that I use six different types of operation. The location of the growth, the age of the patient, the degree of malignancy, the extent of the lesion and the patient's physical status are all very important factors in determining the type of operation to be performed. The hazard of the different procedures must be weighed in making the selection. It is generally accepted that a combined excision carries a mortality of about 12 per cent, contrasting with the 4 per cent mortality of a posterior excision.

## Clinical Notes, Suggestions and New Instruments

### QUININE TREATMENT OF MYOTONIA CONGENITA

WILLIAM A. SMITH, M.D., ATLANTA, GA.

Wolf<sup>1</sup> has recently reported striking benefit obtained by the use of quinine in four cases of myotonia and has concluded that quinine is a specific for this disorder, which has shown practically no response to all previous methods of therapy. I have had an opportunity to confirm this remarkable discovery in three cases, which will be briefly reported.

The familial disease known as myotonia congenita was first described in 1876 by Thomsen, a Danish physician. He himself and twenty members of his family were affected. The disease is characterized by tonic muscular spasms occurring at the start of a movement, which greatly restrict further action. With repeated attempts at movement the spasms relax and the movement gradually becomes more free, until there is no difficulty. After a period of inactivity, however, the spasm occurs on attempted activity. The condition is usually worse when the patient is cold or fatigued. Such tonic spasms, with marked delay in relaxation, occur not only on voluntary movement but also with mechanical or electrical stimulation, and even on reflex contraction such as coughing or sneezing. The skeletal muscles are often greatly overdeveloped, although muscular power may be diminished. The disorder may be generalized or limited to certain muscles. Symptoms usually begin in childhood but sometimes do not appear until puberty or later.

The disease causes considerable disability as well as great embarrassment. On arising from a chair there may be spasms in the legs and inability to move, the patient sometimes falling forward on his face. On attempting to walk fast or run, similar spasms prevent movement until relaxation occurs. Ascending stairs is especially difficult. In shaking hands, the patient often has difficulty in releasing the hand grip. In starting to speak, spasm of the tongue and lips may prevent speech for a few moments. It attempting to chew, spasm of the jaw muscles makes this very difficult at first. Even the ocular muscles may be involved. Neurologic examination usually gives normal results except for the hypertrophied muscles, the tonic spasms on movement and the slow relaxation following contraction.

The etiology is obscure. The condition simulates that produced by veratrine poisoning. By electromyographic studies, Lindsley and Curren<sup>2</sup> have shown that the spasm is a reflex phenomenon, which they thought due to abnormal irritability

of sensory organs in the muscles. Throughout the years no effective remedy has been known, although numerous methods of therapy have been tried.

The effect of quinine in the following cases has been very gratifying:

A white youth, aged 19 years, seen in November 1934, complained of difficulty of rapid movement, which had been present as long as he could remember; whenever he stopped moving, it would be difficult to get started again because of a muscular spasm. When first attempting to walk or run, his legs would become very stiff, which sometimes caused him to fall. In getting up from a chair, his knees would suddenly lock, and he would have to wait for them to relax before being able to move. He had noticed the same difficulty on use of the arms and had difficulty in releasing his hand grip. Later, similar disorders appeared in the muscles of the jaw and tongue with difficulty in starting to chew or to speak. By slowly "warming up" he would be able to continue these movements without difficulty. While attempting to drill in college, he was unable to keep up with the other boys, as whenever they stopped he would be unable to start marching again on command. He had had large muscles since childhood.

The examination showed enlargement of practically all the skeletal muscles. There were tonic spasms on sudden movements, most marked in the extremities. A myotonic reaction with marked delay in relaxation was also present on mechanical and electrical stimulation of the muscles. There were no other significant abnormalities. A diagnosis of myotonia congenita was made.

Sept. 27, 1936, he was given an intravenous injection of quinine dihydrochloride 7½ grains (0.5 Gm.) and in thirty minutes there was practically complete disappearance of all myotonic symptoms, including the myotonic reaction on electrical stimulation. The oral administration of 7½ grains twice daily has been found to be sufficient to maintain freedom from symptoms.

Two sisters, aged 17 and 8 years, had noticed similar though milder symptoms for several years. Both have obtained relief by the oral use of 5 grains (0.3 Gm.) of quinine daily.

### CONCLUSION

The value of quinine in myotonia congenita has been confirmed in three cases.

### OPERATION FOR VOLVULUS WITH RECOVERY

BENJAMIN BOROW, M.D., AND HENRY BOROW, M.D.  
BOUND BROOK, N. J.

When one considers the embryology of the alimentary canal, it is surprising that anomalies of the intestinal rotation are not more common; probably they do occur oftener than they are recorded, owing to the fact that symptoms are absent. Out of a total of forty-eight cases reviewed by Dott, thirty-five were accidentally discovered, as misplacement did not give rise to symptoms or diagnosis was made late.

The case about to be reported is the first, we believe, in which operation was successfully performed when the patient was 4 days old. To understand clearly the condition to be described, the embryologic course will be discussed briefly in the embryo from the fifth week. At this time the canal consists mainly of three parts, foregut, midgut and hindgut, and all are attached by the common dorsal mesentery. The distal portion of the foregut forms the stomach and duodenum. From the midgut, the small intestine and remainder of the tube are formed. From the hindgut, the descending and sigmoid parts of the colon, the rectum and the tubular diverticulum of the allantois are formed. The midgut has a ventral attachment by the vitello-intestinal duct to the yolk sac, which is lost by the fourth week and, as the midgut grows, it is extended into the root of the cord as a temporary umbilical hernia. Rotation of the gut begins about the fifth week while it is in this position, the next stage occurring at about the tenth week. Because of the bulky hernial content, it is impossible for it to return through the narrow umbilical orifice *en masse*. The ileum is forced out, followed by the colon; as the colon elongates, the cecum descends into the right loin. This stage is anticlockwise and turns about the axis of the superior mesenteric artery of 270 degrees from the premature sagittal position of the loop.

1. Wolf, Alexander: Quinine: An Effective Form of Treatment for Myotonia; Preliminary Report of Four Cases, Arch. Neurol. & Psychiat. 36: 382 (Aug.) 1936.

2. Lindsley, D. B., and Curren, E. C.: An Electromyographic Study of Myotonia, Arch. Neurol. & Psychiat. 35: 253 (Feb.) 1936.

The third stage begins about the eleventh week and progresses until birth or a short time after it, being characterized by further descent of the cecum and fixation to the postabdominal wall of certain parts of the intestine, which reaches its normal position at about the fifth month. The importance of this stage is not so much the degree of rotation as the fixation of parts in such a way that displacement, and especially torsion and volvulus, are rendered impossible. The ileocecal angle thus is held steady by adhesion of the cecum and ascending colon.

The only derangement taking place during the first stage of rotation is extorsion of the cloaca, which includes the opening of the ureters, genital ducts and intestinal canal. The derangements occurring during the second stage may be a non-rotation of the midgut loop, a reversed rotation or a mal-rotation of the midgut loop. These, Dott believes, are due to the variation in size of the embryonic umbilical orifice. The third stage of rotation maladjustment would be due to early or delayed fixation of the cecum, the former causing an undescended cecum, the latter an overdescended cecum.

The type of obstruction in this case was a volvulus. The predisposing causes were a narrow base to the loop of intestine, an undue length of mesentery and a point of adhesion at the convexity of the loop, which can act as an axis of rotation. The exciting cause was a peristaltic motility or undue distention of intestine.

#### REPORT OF CASE

J. H., the first child of young parents, was born Sept. 19, 1935. Delivery was normal. The child weighed 6 pounds 13 ounces (3,090 Gm.) and passed meconium from the bowels on the first day. On the second day it passed mucus and about two drops of bright red blood. Rectal irrigations and glycerin and oil enemas were given. The result was a very small amount of flatus.

Physical examination was negative until the fourth day, when some distention was present. On the fourth day a duodenal tube was placed in the stomach and about one-half ounce (15 cc.) of thick viscid bile was withdrawn. Roentgenograms showed a diverticulum of the esophagus and obstruction in the ileum.

Drs. Lathrop and Donovan were called in consultation. The objections of the father and family to operation delayed matters for eight hours. In the meantime the baby's temperature rose from 99 to 103 F. and, during the day, emesis was yellowish green. The infant received 5 per cent dextrose in saline solution previous to the operation and afterward.

The child was operated on under local anesthesia, supplemented by ether. A right paramedian incision was made, the wall being almost one-eighth inch in thickness. Considerable amount of yellowish fluid appeared. The ileum was edematous. There was marked distention of the stomach and upper intestine. The mesentery was markedly indurated, and hemorrhagic areas were present. There was a twist in the longitudinal axis of 360 degrees in a clockwise direction. Above the constriction the intestine was dilated to about the diameter of  $1\frac{1}{2}$  inches, while below it was constricted to about three-eighths inch. The twist was reduced by rotating the whole mass in the anti-clockwise direction and the intestine was returned into as normal a position as possible with considerable difficulty owing to the amount of distention present. The abdomen was sutured in layers and closed without drainage.

Blood transfusion of 20 cc. of the father's blood was given after the operation and repeated the following day; continuous clysis of saline solution and 5 per cent dextrose was also given. Breast milk given after operation was not retained. Lavage was done, returning fecal-like material. Irrigations and stupes were ordered. Enemas of milk and molasses were given. One minim (0.06 cc.) of solution of posterior pituitary was given on the second day. Lavages were done every two to four hours for three days, as the stomach filled with fecal-like material. On the third postoperative day rectal irrigation returned brownish, with a few fecal particles. After the bowels started to move, the baby was able to hold breast milk by mouth in which 5 drops of whisky was added. Diarrhea followed, which was finally controlled by banana powder. One week following the operation the baby weighed 5 pounds 8 ounces (2,495 Gm.) and continued to gain weight slowly. The general condition has been good and at 1 year of age the child weighed 19 pounds 4 ounces (8,730 Gm.).

## Special Article

### THE PHARMACOPEIA AND THE PHYSICIAN

#### DRUG TREATMENT OF CARDIAC DECOMPENSATION

HENRY A. CHRISTIAN, M.D.

BOSTON

*This is one of a series of articles written by eminent clinicians for the purpose of extending information concerning the official medicines. The twenty-four articles in this series have been planned and developed through the cooperation of the U. S. Pharmacopeial Committee of Revision and THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.—ED.*

By cardiac decompensation is meant a combination of symptoms and signs that indicate that the heart by reason of its abnormal condition no longer is able to maintain an efficient circulation. In cardiac decompensation is not included the circulatory failure of acute infectious diseases. Various forms of heart disease may lead to the condition spoken of as cardiac decompensation, such as chronic valvular heart disease, chronic nonvalvular or myocardial heart disease, chronic pericarditis or congenital cardiac lesions. As factors in the production of these forms of heart disease, rheumatic fever and hypertension play very important rôles, the former being the causative factor in almost all the chronic lesions of valves and the pericardium, the latter with arteriosclerosis of the coronary arteries, thyroid disease and possibly the effects of infections being the usual causative factors in the myocardial group. Syphilis of the aorta with aortic insufficiency is the cause of cardiac decompensation in a special group, while the same disease has a definite but quantitatively uncertain, probably slight, part in producing myocardial disease.

In the presence of these cardiac lesions in due course of time will appear the symptoms and signs of cardiac decompensation, of which the most important are breathlessness, cough, edema and cardiac enlargement. As a rule, a correct diagnosis of cardiac decompensation is made easily; not infrequently, however, the etiology in a given case cannot be recognized with certainty. Fortunately, in most patients with cardiac decompensation recognition of the exact etiology plays little part in methods of treatment; the chief exceptions to this are syphilis and thyroid disease, and here the use of the Wassermann reaction and determinations of basal metabolism along with other evidence give quite a clear clue to these relationships of etiology utilizable in treatment.

Given then any of these conditions with resultant cardiac decompensation sufficiently marked to interfere with the patient greatly, certain therapeutic procedures are indicated for each patient. Such a patient needs primarily physical rest; with few exceptions this should be bed rest with the patient comfortably propped in a half sitting posture; in a small number of cases a chair position is required for the first few days.

Since many cardiac patients have been prevented by their symptoms from getting sufficient sleep, a very important part of the early treatment is to give a drug that will produce a good night's rest; for this purpose hypodermic injection of morphine sulfate, from one-sixth to one-four grain (10 to 15 mg.), is most effective, and this can be repeated for a night or two until

other therapeutic measures have so improved the circulation that the patient will sleep satisfactorily without any further sedation.

The drug of greatest value in the treatment of cardiac decompensation is digitalis. With extremely few exceptions digitalis is effective when given by mouth, and no form is superior for mouth dosage to the very simplest form of the drug, pills or capsules of powdered digitalis leaves. For patients with marked decompensation not having received digitalis in any form within the past week the initial dose should be  $7\frac{1}{2}$  grains (0.5 Gm.) to be repeated in four hours and usually again four hours later, the patient thus receiving  $22\frac{1}{2}$  grains (1.5 Gm.) in the first eight hour period. After this, 3 grains (0.2 Gm.) or  $1\frac{1}{2}$  grains (0.1 Gm.) three times a day should be given and continued until a therapeutic effect or some evidences of toxicity result. The original directions of William Withering in 1783 as to giving digitalis cannot be improved on: "Let the medicine be continued until it either acts on the kidneys, the stomach, the pulse or the bowels; let it be stopped upon the first appearance of any one of these effects."

Tincture of digitalis may be substituted in mouth dosage for the powdered leaves if for any reason that seems desirable; rarely, however, in my experience is that the case; if for no other reason, the convenience of pills and capsules would give a preference to powdered leaves over the tincture; however, it has always seemed to me that the whole leaf has a therapeutic superiority to the alcohol soluble portions present in the tincture.

The foregoing dosage should be increased for cases of greater severity and for very large patients. Conversely, for patients with less marked degree of cardiac decompensation and for small patients the initial large doses may be curtailed or abandoned. This abandonment of the large initial doses particularly is indicated when the patient previously has been getting digitalis in any considerable dosage.

In all of these statements of dosage, it is assumed that all preparations of digitalis are of standard Pharmacopeial activity as determined by the biologic test contained in U. S. P. XI.

For patients extremely ill, in whom a digitalis effect must be prompt to save life, intravenous medication is indicated. For this, strophanthin or ouabain is best, the intravenous dosage being from 0.5 to 1 mg., not to be repeated within twenty-four hours and not to be used in a patient recently having received previously digitalis in other form in other than very small dosage. Extremely few patients need this intravenous form of therapy.

In some patients in whom nausea and vomiting prevent mouth dosage, strophanthin or ouabain, as described, can be used until the gastric symptoms subside sufficiently to permit a return to mouth dosage. In this type of patient, instead of strophanthin or ouabain intravenously, tincture of digitalis can be given by rectum in a dosage of 1 or 2 drachms (5 to 10 cc.) once or twice daily, followed by a small amount of physiologic solution of sodium chloride, the injection being preceded by a bland cleansing enema.

At present there is no advantage to be obtained by using any other than Pharmacopeial preparations of digitalis, notwithstanding the many proprietary digitalis preparations that are being offered with great enthusiasm to the medical profession, their dispensers making many claims for their superiority, claims that seem not justified as far as my own clinical experience goes.

In some patients with cardiac decompensation, edema is marked. Often it disappears rapidly as the result of the digitalis and rest therapy. When it does not, diuretic drugs are indicated. For mouth dosage one of the xanthin group can be used, as theobromine with sodium salicylate, theophylline or theophylline with sodium acetate. These should be given in two or three doses at two hour intervals every second or third day, the first dose being given early in the morning, the single dose of the theobromine group being from  $7\frac{1}{2}$  to 15 grains (0.5 to 1 Gm.) and of the theophylline group from 5 to  $7\frac{1}{2}$  grains (0.3 to 0.5 Gm.).

In case the xanthin group of diuretics are not sufficiently effective, the mercurial diuretics such as merbaphen (novasurol) should be utilized, for they are more effective as diuretics than are the xanthin group. However, they are not effective by mouth dosage but must be given parenterally, preferably intravenously, though they may be given intramuscularly with risk of some local irritation. These mercurials are prepared in ampules ready for parenteral dosage as a 10 per cent solution of the drug. The dose of this preparation is from 1 to 2 cc. by either route at two or three day intervals. Like the xanthin diuretics, they should be given early in the morning, so that the major diuresis ends before bedtime. Of the mercurial diuretics, salyrgan and mercupurin, not so far included in the Pharmacopeia, definitely are less toxic and more effective than merbaphen and so are preferable. At present there are available mercurial preparations of salyrgan and the mercurial portion of mercupurin, which are effective by rectum in the form of a suppository; the availability of these at times is a great help in the management of edematous cardiac patients.

To obtain the best effects from mercurial diuretics, often ammonium chloride or ammonium nitrate needs to be given for from twenty-four to forty-eight hours prior to using the diuretic in doses of 15 grains (1 Gm.) four times a day. These drugs should be given well diluted with water or fruit juice or in the form of tablets, coated so as to prevent solution by the gastric juice.

When there is hydrothorax present, this should be removed in the beginning of the treatment by tapping. It is inadvisable to attempt to treat this situation by diuretic drugs. Ascites usually disappears under diuretic therapy, as just described; failing to do so, mechanical removal is indicated.

In patients of this group in whom coronary circulation is defective, it is believed by some that improvement in the rate of coronary flow with resultant dilatation of the collateral vascular channels and eventual improvement in myocardial function can be brought about by the use of theophylline with ethylenediamine in doses of  $1\frac{1}{2}$  grains (0.1 Gm.) three times a day, the drug diluted in half a glass of water to decrease gastric irritation. I myself remain unconvinced of any great effectiveness from this drug for this purpose.

In a rare patient with cardiac decompensation having auricular fibrillation in whom digitalis fails to bring about improvement, betterment may come from making the cardiac rhythm regular by the use of quinidine sulfate. To accomplish this, after a test of quinine susceptibility by a dose of 3 grains (0.2 Gm.) of the drug, quinidine sulfate then should be given every four hours in a dose of 6 grains (0.4 Gm.) until rhythm becomes regular, or even larger dosage may be used. However, it is well to remember that to carry out such treatment has a certain definite, though small, risk, as fatalities

may follow quinidine sulfate dosage. If a patient receiving quinidine sulfate shows signs of collapse, caffeine in some of its forms (caffeine, citrated caffeine, and caffeine with sodium benzoate) should be given at once intravenously in 15 grain (1 Gm.) doses, or, if the pulse has failed, intracardiac injection should be attempted. At the same time artificial respiration should be instituted.

Active catharsis now rarely is instituted for patients with cardiac decompensation. If it is considered desirable, magnesium sulfate or compound jalap powder may be used. Mild catharsis to prevent constipation often is desirable for these patients; some form of cascara (extract of cascara, fluidextract of cascara, aromatic fluidextract of cascara) as a rule is satisfactory for this purpose. This failing, other procedures as advised in the article in this series on cathartics can be followed.

If the cause of the cardiac lesion inducing cardiac decompensation is syphilis, the syphilis should be treated after the cardiac decompensation has been managed in the ways described or before it develops. This is to be done with iodide, mercury and bismuth preparations as described in the article of this series describing the treatment of syphilis. As to the use of arsphenamine in syphilis of the aorta there is difference of opinion; my experience indicates that it is of value and that, if used cautiously, it is safe. Mercury or bismuth compounds should be given first for several doses at weekly or biweekly intervals and then followed by arsphenamine, the first doses of the latter being 0.2 Gm. Later the dose can be increased to 0.3 Gm. and eventually to 0.4 Gm. if there are no untoward reactions, the arsphenamine being given once or twice a week. When pain is present as a symptom of syphilitic disease of the aorta, treating the syphilis, as just described, often is very beneficial as concerns that symptom. Statistics seem to indicate that such treatment of the syphilis has practically no influence on cardiac decompensation but that it may slow the progression of the syphilitic lesion and so prolong life. Antisyphilitic treatment should be instituted as soon as the lesion is diagnosed, preferably before cardiac decompensation is in evidence. Those with experience with syphilis of the myocardium generally advise against arsphenamine but use the other antisyphilitic drugs in its treatment.

When hyperthyroidism is a causative factor in cardiac decompensation, proper surgical treatment of the thyroid should be carried out as soon as cardiac decompensation has been controlled sufficiently to make subtotal thyroidectomy reasonably safe. The results are very satisfactory.

With the form of cardiac disease due to thyroid deficiency or myxedema, striking improvement promptly follows properly adjusted mouth dosage of thyroid gland substance. Care must be taken, however, not to give it so as to restore too rapidly the thyroid deficiency, since in so doing one may place too great a burden on the heart and produce symptoms in this way, especially anginal pain. It is well to begin with a dosage not greater than one-fourth grain (15 mg.) of a thyroid gland preparation standardized as to efficiency by the method described in the Pharmacopeia. Determinations of the rate of basal metabolism serve as an effective guide to treatment in these patients.

During the early stages of treatment of cardiac decompensation, diet should be limited to small amounts of milk, from 800 to 1,000 cc. daily. After a few days, carbohydrate and egg should be added. Later a more

liberal diet based on the caloric requirements of the patient should be given. Frequent small feedings are indicated so long as decompensation persists. Fluid intake in these patients should be restricted to from 1,200 to 1,500 cc. As many of these patients are overweight, the diet should be gaged so as to bring about proper reduction in weight until the patient that has been overweight is from 10 to 15 pounds (4.5 to 7 Kg.) underweight; but this reduction must be carried out slowly. The diet must be adequate in constitution to prevent vitamin deficiency. Many cardiac patients need added vitamin in their diet, and some of these may be supplied by using properly standardized preparations as well as by giving diet adequate with respect to them.

Practically all patients with cardiac decompensation, after that has been treated satisfactorily, need to continue to take digitalis indefinitely in amounts just short of causing toxic disturbances. For the majority of patients this is  $1\frac{1}{2}$  grains (0.1 Gm.) of powdered leaves, once or twice daily; a few patients do better, on either more or less than this, as determined by trial.

Peter Bent Brigham Hospital.

## Council on Pharmacy and Chemistry

### NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

**TETRACHLORETHYLENE.**—" . . . contains not less than 99 per cent and not more than 99.5 per cent of  $\text{CCl}_2\text{CCl}_2$ , the remainder consisting of alcohol." N. F.

For standards see the National Formulary under Tetrachlorethyleneum.

**Actions and Uses.**—Observations of many workers have shown that tetrachlorethylene is a useful anthelmintic for the treatment of hookworm infestation. It has been used against other worms with less success, although there is some evidence that it is useful in *Trichuris* infestation. It may be lethal to *Ascaris* but its use in that infestation is not advised because of the danger of causing migration of the worms. It is the consensus of the investigators that tetrachlorethylene is less toxic than carbon tetrachloride ( $\text{CCl}_4$ ) and at least as efficacious as the latter drug. It has a further advantage over carbon tetrachloride in that it does not lower the guanidine content of the blood, which is important in cases exhibiting a calcium deficiency. Untoward reactions are rare, but giddiness, vomiting and drowsiness have been reported in some cases. It is probably better to keep the patient (especially children) in bed during the treatment.

**Dosage.**—From 1 to 3 cc., depending on the age of the patient. Tetrachlorethylene is usually given in soft gelatin capsules but has also been administered to children on a lump of sugar. The gastro-intestinal tract should be thoroughly emptied before administering tetrachlorethylene. Fats and alcohol must be avoided, because they favor absorption of the drug. A dose of tetrachlorethylene should be followed by a saline cathartic of sodium or magnesium sulfate. One dose frequently suffices, but if necessary it may be repeated once after a period of from ten days to two weeks.

**NOTE.**—Broken capsules should be discarded; the solution should never be employed if it has been exposed to the air for more than a very brief time, because of the possibility of phosgene formation by decomposition.

**Tetrachlorethylene-Calco.**—A brand of tetrachlorethylene N. F., marketed in soft gelatin capsules each containing 1 cc. of tetrachlorethylene.

Manufactured by Calco Chemical Co., Inc. (a division of the American Cyanamid Co.), Bound Brook, N. J. No U. S. patent or trademark. Tetrachlorethylene-Calco, 1 cc.

## Council on Foods

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT.  
FRANKLIN C. BING, Secretary.

### LAMBERT'S V. M. C. AND V. M. P. NOT ELIGIBLE FOR THE LIST OF ACCEPTED FOODS

The W. H. Lambert Laboratory of St. Louis presented two products which they call V. M. C. (initials standing for vitamins, minerals, cereals) and V. M. P. (meaning vitamins, minerals, protoplasm) with the request that they be considered by the Council on Foods of the American Medical Association. Proposed advertising copy, descriptions of the products and other information required by the Council were also presented.

The product V. M. C., according to the information which the company has supplied, is a powdered mixture of sugar, cocoa, powdered skim milk, hard winter wheat, malt extract, wheat germ meal, dicalcium phosphate, brewers' yeast, karaya gum, alfalfa leaf meal and salt, flavored with vanillin. V. M. P. is stated to be a powdered mixture of karaya gum, alfalfa leaf meal, dehydrated lemon juice, brewers' yeast, wheat germ, dicalcium phosphate and citric acid. The company later informed the Council that the products have been fortified with a fish liver oil concentrate supplying vitamins A and D. The products are referred to by the company as "special purpose" foods. The Council cannot accept such hodgepodge mixtures for its list of accepted foods.

In the heyday of "patent medicine" interests a nostrum was essentially a mixture of drugs, endowed with a proprietary name, and exploited with unwarranted therapeutic claims. Today the manufacturer of "health foods" puts together a pot-pourri of alfalfa and other products, adds a little flavoring, and claims that the mixture is not a drug but a food. The composition of such bizarre products is generally predicated on the theory that the diet is deficient in a number of dietary essentials and that, if one mixes together various salts and inexpensive fat products with a little flavoring, it can be foisted on the unfortunate public as a panacea for whatever human imperfections and ailments the clever copy writer cares to mention. The advertising claims rival those made for the alleged virtues of the old-time "patent medicines." The ignorance of nutrition displayed by such promoters is equaled only by the extravagance of their claims.

Could the blatant copy of "patent medicine" concerns have produced anything more fanciful than the statements first proposed for Lambert's V. M. C.:

"Helps increase weight, aids digestion, stimulates appetite, builds up the blood, improves health and complexion, feeds nerves, benefits teeth, bone development, laxative."

The claims for V. M. P. are equally extravagant:

"V. M. P. helps reduce surplus fat in a safe natural way. It improves the complexion, feeds nerves, benefits teeth, bone development, builds up blood, aids digestion and naturally eliminates constipation."

The advertising copy submitted for a proposed booklet describing the products expands on the absurd claims described on the labels. It introduces also amazing dietary advice on how to become beautiful both in face and in figure. The initial heading reads "Have an alluring figure, charm and health." There are many subheadings, such as "The secret of glamorous, attractive women." One is directed how to gain from 15 to 50 pounds in a new, quick, easy way, and, immediately following, how to reduce "ten to thirty pounds safely." The reader is told at the onset that "beauty secrets are between the covers of this book." Further on he is told that the "diet in this one volume tells you exactly how you can be as lovely as the stars if not lovelier."

From information which has more recently come to the attention of the Council, it appears that the label has been revised somewhat. A picture of an artistically posed young woman (unclothed except for a pair of shoes) has been substituted for much of the written material on the submitted label. The inference that the product can create such beauty, however, remains.

The Council on Foods believes the promotion of products such as V. M. C. and V. M. P. portends much harm, particularly because of the false sense of security that may be gained from their inadvised use. The Council voted, therefore, that Lambert's V. M. C. and Lambert's V. M. P. be not included in the list of accepted foods and that the company be informed of this action. This was done and an unsigned communication on the firm's letterhead was received; this was returned for proper signature. No further communication has been received from the firm and the Council has authorized publication of the foregoing report.

### ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

FRANKLIN C. BING, Secretary.

#### VIOBIN

*Manufacturer.*—VioBin Corporation, Chicago.

*Description.*—Partially defatted and dehydrated wheat germ.

*Manufacture.*—Commercial wheat germ is extracted by organic solids to remove the fat. The solvent and oil are removed, the defatted wheat germ is treated to volatilize the traces of organic fat solvents, and the product is packed in cans.

*Analysis* (submitted by manufacturer).—Moisture 7.0%, total solids 93.0%, ash 4.9%, fat (ether extract) 2.1%, protein (N  $\times$  6.25) 38.0%, crude fiber 2.9%, carbohydrates other than crude fiber (by difference) 45.1%. Analysis of inorganic constituents showed K 1.08%, Ca 0.067%, Mg 0.353%, P 1.1%, Mn 0.009%, Fe 0.011%.

*Calories.*—3.6 per gram; 102 per ounce.

*Vitamins.*—Vitamin B<sub>1</sub>, from 14 to 18 units per gram (Sherman Chase), from 7 to 9 units per gram (International).

*Claims of Manufacturer.*—A special purpose food processed to prevent the possibility of development of rancidity; a rich source of vitamin B<sub>1</sub> and contains vitamin G.

#### (a) BLISS CRYSTAL WHITE SYRUP

#### (b) BLISS GOLDEN SYRUP

*Packer.*—Bliss Syrup and Preserving Co., Kansas City, Mo.

*Description.*—(a) A table syrup; corn syrup sweetened with sucrose syrup and flavored with vanilla. (b) A table syrup; corn syrup flavored with refiners' syrup.

*Manufacture.*—(a) Same as Bliss Pancake Crystal White Brand Syrup (THE JOURNAL, Nov. 18, 1933, p. 1635). (b) Same as Bliss Pancake Brand Golden Syrup (THE JOURNAL, Oct. 28, 1933, p. 1393).

*Claims of Manufacturer.*—Recommended for use as an easily digestible and readily assimilable carbohydrate supplement to milk in infant feeding and as a syrup for cooking, baking and the table.

#### BELLWOOD BRAND ORANGE JUICE

*Distributor.*—W. H. Williams Company, Inc., Richmond, Va.

*Packer.*—TreeSweet Products Company, Los Angeles.

*Description.*—Heated California Valencia Orange Juice practically equivalent to fresh orange juice in vitamin C content. The same as TreeSweet Pure California Orange Juice (THE JOURNAL, June 15, 1935, p. 2187).

#### BIG M BRAND HAWAIIAN PINEAPPLE CRUSHED AND SLICED

*Distributor.*—The Merchants Company, Hattiesburg, Miss.

*Packer.*—Hawaiian Pineapple Company, Ltd., San Francisco.

*Description.*—Canned pineapple packed in concentrated pineapple juice with added sucrose. The same as Dole canned pineapple (THE JOURNAL, April 8, 1933, p. 1106).

SATURDAY, JANUARY 2, 1937

## CHEMOTHERAPY IN STREPTOCOCCIC INFECTIONS

Since the significant paper of Domagk<sup>1</sup> in 1935, renewed interest has developed in the possibility of chemotherapy in streptococcic diseases. A dark red dye synthesized by Mietzsch and Klarer seemed promising in animal protection experiments. The dye is the hydrochloride of 4'-sulfamido-2:4-diaminoazobenzene. Its toxicity both for mice and for human beings is remarkably slight. In Domagk's report "prontosil," as this dye has been named, was administered by stomach tube to twelve of twenty-six mice an hour and a half after intraperitoneal inoculation with virulent hemolytic streptococci of human origin. All of the twelve that received the dye survived at least seven days. Of the remaining fourteen animals, which served as untreated controls, thirteen were dead within three days and the fourteenth died on the fourth day. Partial corroboration of Domagk's work has been published by Levaditi and Vaisman and considerable suggestive clinical data have been supplied by other German and French investigators. In this issue of THE JOURNAL Long and Bliss<sup>2</sup> indicate the interesting results of their recent investigations at the Johns Hopkins University Hospital.

Colebrook and Kenny<sup>3</sup> have reported other experimental and clinical observations on prontosil and a more soluble modification, the disodium salt of 4'-sulfamido-phenyl-2-azo-7-acetylamino-1-hydroxynaphthalene 3:6-disulfonic acid. Their preliminary mouse experiments failed to confirm Domagk's results. When, however, a different streptococcus strain was used which had been transmitted through a series of twenty-three mice and had acquired high virulence for these animals, the results differed from their first experiments. With the latter strain they began at once to get striking curative results in mice when the prontosil soluble was

administered subcutaneously or by stomach tube within a few hours after the intraperitoneal injection of streptococci. In fact, the results indicated quite clearly, they believed, that the administration of the drug does exert some curative effect on infections by these hemolytic streptococci in the mouse. The customary evolution to peritonitis and septicemia could be checked in the majority of the animals if treatment was begun within three hours of the injection of the culture. A group of twenty-four mice was tested for the prophylactic effect of prontosil. Of the twelve which received 50 mg. of prontosil subcutaneously before injection of the streptococci, only three died before the seventh day. Of the twelve control mice, nine died before the fourth day. When the surviving animals were subsequently killed, a large deposit of undissolved prontosil was found at the site of injection. It thus seems probable that the prophylactic effect observed was due to slow absorption from this depot. The mode of action of prontosil is obscure. The chief positive facts which emerge from their investigations are that multiplication of streptococci in the peritoneal cavity is prevented if the dye is administered within a few hours. It appears unlikely that the cocci are destroyed either by the drug itself or by some compound formed from it in the animal body. In vitro experiments made with human and rabbit serums disclose no evidence that administration of the drug promotes more active killing of the streptococci by the whole blood. Human leukocytes are but little affected. Apart from the slight growth-retarding influence exhibited by the serum of treated cases there is therefore not much to suggest that either the blood fluids or the blood cells play a predominant part in checking the invasion of the tissues by the streptococci. The hypotheses that the formation of a protective capsule by the streptococcus is interfered with, that the cocci in treated animals ceases to elaborate certain toxic products, that the drug activates the reticulo-endothelial system are all lacking in experimental support.

Buttle and his collaborators<sup>4</sup> have investigated a third related compound, paraaminobenzenesulfonamide base (known commercially as "prontylin") for its protective action in streptococcic infections of mice. The efficacy of a drug for protecting against streptococcic infection can be assessed, they believe, by two criteria: (1) an estimate of the number of average lethal doses of cocci against which the drug will protect when given to infected mice under optimal conditions for action and (2) an estimate of the latest time after infection when its administration will still be operative in saving the animals. The protective action of paraaminobenzenesulfonamide base was tested with six different strains of virulent streptococci. There was a definite difference in the duration and number of survivals between untreated and treated mice, and considerable difference

2. Long, P. H., and Bliss, Eleanor A.: Para-Amino-Benzene-Sulfonamide and Its Derivatives, this issue, p. 32.

3. Colebrook, Leonard; Kenny, Meave, and the members of the honorary staff of Queen Charlotte's Hospital: Treatment of Human Puerperal Infections, and of Experimental Infections in Mice, with Prontosil, Lancet 1: 1279 (June 6) 1936.

4. Buttle, G. A. H.; Gray, W. H., and Stephenson, Dora: Protection of Mice Against Streptococcal and Other Infections by p-Aminobenzenesulfonamide and Related Substances, Lancet 1: 1286 (June 6) 1936.

in the protection against different strains and in the optimal dosage of the drug. Experiments with staphylococci and pneumococci failed to show any protection. Those with meningococci were uncertain and require further investigation. These observations tend to minimize the likelihood of the dye acting directly and exclusively on the reticulo-endothelial system.

Colebrook and his co-workers also reported briefly on certain clinical experiences with prontosil. Thirty-eight patients with puerperal fever due to hemolytic streptococci were treated by oral and intravenous or intramuscular doses of prontosil and prontosil soluble. The impression was that in many of the more severe cases the drug exerted a definitely beneficial effect manifested by a prompt fall of temperature and remission of symptoms. This was partially corroborated by the death rate, which was 8 per cent in the thirty-eight cases treated, 26.3 per cent in the thirty-eight cases admitted immediately prior to the use of the drug, and between 18 and 28.8 per cent for the four years 1931-1934.

The studies thus far reported abroad on the use of these dyes in the treatment of streptococcic infections are now apparently substantiated to a considerable extent by subsequent investigations. The animal experiments in this country need still further corroboration and there should be efforts to determine the mode of action under different circumstances and in different animals. The clinical observations reported present the usual optimism but there must be adequate clinical controls. Much painstaking effort is necessary before the use of such dyes can be placed on a completely scientific basis. It may be hoped, however, that further investigations will disclose a definite group of disorders characterized by high virulence and mortality which can be materially helped by appropriate chemotherapy.

### BRUCELLOSIS

The *Brucella* group of micro-organisms is commonly divided into *Brucella melitensis* (the goat strain), *Brucella abortus* (the bovine strain) and *Brucella suis* (the porcine strain), all of which may cause brucellosis in man. In a recent review of brucellosis in Iowa, Jordan and Borts<sup>1</sup> point out that infected cows and hogs are the usual source of infection in human brucellosis in that state. With the exception of hogs, which are known to be infected only with the porcine strain, animals may be infected with any of the three closely related types of *brucella* germs. The symptoms of the disease are weakness, sweating, fever, chills, loss of weight and aching. While treatment at present consists largely in relieving the symptoms of discomfort and the use of medicinal preparations aimed at shortening the duration of illness, some cases have been treated successfully by subcutaneous injections of a *Brucella* vaccine. During nearly a decade in which the disease

has been recognized in Iowa, one or more cases have been reported from all counties in the state. The State Hygienic Laboratories have had a total of about 2,254 positive blood tests during the ten years.

People who live on the farms are more subject to brucellosis than those who live in cities. On the farms the disease affects more farmers than farm wives, because the men come in contact with hogs and cows to a greater extent than do the women. From 1933 to 1935, 319 cases of undulant fever were reported to the Iowa State Department of Health. These have been classified according to residence in rural or urban areas and according to occupation. About half of the number occurred in rural areas, most of which were in male farm workers. In the urban districts the most commonly involved were merchants and professional people, followed by packing house workers, housewives and school children. Of the 318 patients classified according to age and sex, 73 per cent were male and 27 per cent female. The number of male cases of brucellosis exceeded the female in all age groups except the very young and those over 60.

More cases of undulant fever are reported during the summer months than during the cold season. This may be accounted for on the basis of increase (1) in discharges from infected animals following calving and farrowing, (2) in types of contact with infected animals, (3) in raw dairy products containing *Brucella*, and (4) in rate of multiplication of the organisms in dairy products owing to the higher temperature. In tracing undulant fever to the animal source, the agglutination test, blood culture and tests of animals and of milk specimens are the most important available methods. The control of the disease is dependent on measures of prevention of transmission through daily contact with infected animals or their environment. Prevention should be aimed especially at eradication of Bang's disease in cows, pasteurization of dairy products, vaccination, and limiting the chances for exposure in all forms of direct contact with animals that may be infected.

### ARTIFICIAL RADIOACTIVE MATERIAL

The possibility of applying artificial radioactive elements to biologic research and radiation therapy has aroused much interest. Some investigators have prophesied that artificial radioactive elements may eventually replace radium and radon for certain types of therapy.

M. and Mme. Joliot, son-in-law and daughter of the late famous Mme. Curie, were awarded the Nobel Prize (1934) for their discovery of artificial radioactivity. They bombarded boron with alpha rays, making a substance called radionitrogen, which gave off radiation resembling the radiation from radium. The life of the product, which is about fourteen minutes, is insignificant compared to the life of radium. Other investigators in many parts of the world have followed this line of research. For the bombarding medium some have

1. Jordan, C. F., and Borts, I. H.: Brucellosis in Iowa, Iowa Pub. Health Bull. 50:4 (July, Aug., Sept.) 1936.

used the neutron, the electrically uncharged elementary particle possessing nearly the same mass as the hydrogen atom, and others have used the deuteron, the charged atom of heavy hydrogen. To date, more than forty elements have been made artificially radioactive, and the half-life of this radioactivity varies from a few seconds to about fourteen days.

In the radiation laboratory in the Department of Physics, University of California, a device called the cyclotron has been invented, which creates exceedingly high velocities of deuterons.<sup>1</sup> The high velocity of these deuterons is generated between the poles of a huge electromagnet. Essentially, its operation consists of deuterons being continuously accelerated round and round in a spiral. This gives them their high speed energy, which otherwise would be unobtainable. The deuterons reach a wall of one electrode and pass out of it through a slit; then they pass through a thin vacuum-tight metal window. Materials such as common salt are placed at this point. It is possible to bombard the sodium in the salt and make a product known as radiosodium. The half-life of radiosodium is fifteen and one-half hours. The chief advantages of these products would seem to lie in the homogeneity of their radiations, the suitability of their half-lives for therapeutic uses, and the nontoxicity of their decay products. Several other research laboratories have acquired cyclotrons, and more are obtaining them now.<sup>2</sup>

The life of the radioactive substance is short and therefore would probably not be as detrimental to the human being as radium when it is taken internally. More experimental work is required. At present it will be retarded because of the unavailability of machines to produce artificial radioactive materials. Other instruments have been developed for this purpose, but the cyclotron seems to present the greatest possibilities. Its bulk of several tons and its great expense necessarily restrict research activity except in localities where the cyclotron is available.

## Current Comment

### ORIGIN OF FECAL FAT

The products of digestion in the gastro-intestinal tract are not in the body until they have passed through the wall of the intestine. Two circumstances have combined to render difficult the precise determination of the so-called utilization of the major food materials and the evaluation of the factors influencing it; namely, the great difficulty in securing samples of blood and lymph at the immediate site of absorption from the intestine and the now well known fact that materials are excreted into the enteric canal as well as absorbed from it. Thus the fecal lipid may represent either unabsorbed fat, fat that has been excreted, or both. The presence of

bile is an important factor in the digestion and absorption of fat; in its absence there is a definite increase in fecal fat. In order to determine the origin of the lipid in the feces of subjects with bile fistulas, Shapiro and his co-workers<sup>1</sup> have fed, together with the diet, fat containing a known proportion of deuterium. This isotope<sup>2</sup> of hydrogen apparently behaves as ordinary hydrogen in metabolism and yet can be quantitatively determined in compounds containing it; it serves as an identifying "mark" for substances of which it is a part. The proportion of deuterium in the fecal fat equated with that in the food fat should thus serve as a reliable index to the origin of the fecal fat. It was found that of the deuterium-containing fat given with the food only 30 and 35 per cent respectively appeared in the feces of the two subjects studied. It was concluded "from these analyses that the remaining 65 to 70 per cent of the diet fatty acid was absorbed and that the greater part of the fecal fat in our patients originated from the fat secreted into the intestinal tract." The subjects received 0.7 and 2.1 Gm. of the deuterium-containing fat in the diet; it appears that such small amounts of fat can be largely absorbed even in the absence of bile and that, if all the food fat followed the course of the deuterium-containing fat, fecal lipid in the absence of bile has, to a large extent, an endogenous origin.

### CONTROL OF SYPHILIS

The Prosser White Oration, delivered by Dr. John H. Stokes before the St. John's Hospital and the London Dermatological Society, June 15, 1936, has been recently printed by the Public Health Service of the U. S. Treasury Department.<sup>1</sup> Much of this address considers the failure to control the spread of syphilis as effectively as present knowledge of the disease would imply. Stokes points out some shortcomings in the laboratory tests for syphilis. Thus, he believes that the darkfield examination has serious limitations as a practical diagnostic device. Similarly, the serologic tests for syphilis require a well organized mechanism, which partially inhibits their universal use. Furthermore, he points out as others have done that the clinical knowledge of the course and symptomatology of syphilis as well as the attempt to eliminate it is frequently underdeveloped in medical practitioners. The epidemiology of the disease also comes under consideration by Stokes. Modern treatment, while more effective than earlier methods, is more intricate and more prolonged and hence is frequently abandoned before optimal effects have been obtained. Stokes does not feel, however, that the clinic as such, as opposed to treatment by individual physicians, is the answer to the problem. He believes that better clinics rather than more clinics, and better trained physicians, should be more effective than requiring all treatment to be performed in clinics. Intensive effort with regard to the development of a public health policy for syphilis control and to widespread educational efforts offers the most promising method of controlling this still flourishing disease.

## The New Bulletin

For some years, Fellows of the American Medical Association have received the AMERICAN MEDICAL ASSOCIATION BULLETIN each month, except for the vacation season. It was a separate publication issued as the organ of the House of Delegates to keep the Fellows of the American Medical Association apprised of developments from the point of view of organizational work. It contained also discussions of subjects of governmental, economic and social importance.

Since the coming years are likely to be exceedingly critical as far as concerns evolution in the nature of medical practice, the Board of Trustees has felt it expedient to discontinue the *Bulletin* and to substitute therefor a regular supplement to THE JOURNAL to be devoted to the organizational, economic, business and social aspects of medical practice. The material on this and the following seven pages constitutes the first section of this kind. It is proposed to publish a similar section each week, separately paged from THE JOURNAL but nevertheless an integral part. In order to make a more definite distinction of this material from that largely scientific, the material here included is typographically different and will be indexed as well as paged separately. Enough material is already available to indicate to some extent the nature of the subject matter for the next several months.

The American Medical Association has recently rebuilt its headquarters office in the interests of economy and efficiency. It is proposed to issue a series of articles adequately describing the headquarters office, including the personnel and the work of each of the departments. This will be followed by a history of the Association. The

Bureau of Medical Economics has completed an extensive study of rural medical service by individual states and will make available the results of this survey during the next eight to ten weeks. Reports will also begin to appear shortly covering the annual sessions of the secretaries and editors of the state medical societies, whose interests lie very close to the daily work of the physician. In the supplement there will also be available a regular space for notices of official meetings, such as those of the various councils and committees. The work of the Woman's Auxiliary, which was formerly included in the BULLETIN, has now assumed such proportions as to merit a special page for its activities.

The new BULLETIN will concern also a number of business aspects of medical practice. We have in mind particularly articles concerned with the investments of the physicians, his equipment, the establishment of collection agencies, telephone service, and credit rating bodies. Here also will be discussions of problems of taxation and other business questions.

The speed of modern civilization and the great widening of the scope of the activities of the American Medical Association are more than adequate warrant for speeding up the informational service in relationship to this work by having regular weekly announcements rather than an occasional monthly publication. The editors will be much interested to have from readers suggestions as to material that may well be included in a publication of this kind and also their personal views as to the extent to which such a publication will meet the increasing needs of the medical profession for reliable material in the field of medical economics.

## The Home of the American Medical Association

*NOTE.—This is the first of a series of articles describing the headquarters office of the American Medical Association and the work of its various departments. Subsequent articles will appear week by week, until the series is completed, after which the articles will be published in pamphlet form.—Ed.*

### THE FIRST HOME

When the American Medical Association decided in 1883 to publish a journal, Dr. N. S.

Fig. 1.—Above, at left, property first purchased at corner of Dearborn Street and Grand Avenue, containing five houses; the two at the left occupied the site of the first building. Below, at left, three-story and basement building originally erected, and occupied in December 1902. Above, at right, building of the Association as it appeared in 1910, a fourth story having been added in 1905; also remaining houses of original purchase. Below, at right, home of the Association headquarters from 1911 to 1923.

Davis of Chicago, who was the leader of the movement, became its first editor. Previous to that time the Association had a small membership—about 3,000—and published merely an annual transactions. There were no headquarters, except the office in which the permanent secretary, Dr. Atkinson, who lived in Philadelphia, conducted his practice. In fact, except for the time when the Association was in its annual session, its functions were nonexistent. The first editorial offices were those of Dr. N. S. Davis, and the first number of *THE JOURNAL* was issued from those offices on July 4, 1883. Thereafter as type and other equipment were purchased, *THE JOURNAL* moved successively to 68 Wabash Avenue (Nov. 23, 1888), to 86 Fifth Avenue, now Wells Street (Sept. 1, 1894), and to 61 Market Street (May 1, 1896). Each of the new locations was made necessary by the growth of *THE JOURNAL*. By 1896 it had reached a circulation of 8,000 copies weekly, and by 1902 this had increased to more than 25,000 copies weekly. Comparative figures indicate a circulation of 53,000 for 1910, 64,500 for 1915, 79,000 for 1920, 85,600 for 1925, 95,000 for 1930, 91,600 for 1935 and 95,400 for November 1936.

### THE PERMANENT HOME

In 1902 the growing demands for space prompted the Board of Trustees to consider the purchase of real estate for a permanent home. In March 1902, property was purchased at the northeast corner of Dearborn Avenue and Indiana Street, now Grand Avenue. This property consisted of 100 feet on Dearborn by 80 feet on Indiana, containing five two-story and and basement houses, at a cost of \$42,000. The value of the ground has increased materially. The first building of the American Medical Association was a three-story structure, 40 by 80 feet, with a high basement, of brick with stone trimmings, as shown in the illustration. Its cost was \$35,000.

Thereafter, an adjacent plot of ground 40 by 100 feet was purchased in June 1903 at a cost of \$15,000. This made the entire ground space owned by the Association 100 by 120 feet. Subsequently, additional ground was purchased on Grand Avenue, so that the plot owned by the Association is now 100 feet on Dearborn Street and 280 feet on Grand Avenue.

As has been mentioned, the circulation of *THE JOURNAL* rose steadily. Gradually the Coun-

Fig. 2.—Six-story brick building before reconstruction.

cil on Medical Education and the Council on Pharmacy and Chemistry, whose histories will be related at a later date, and the Directory

department were established. Each of these expansions in service necessitated more room. The original plant had been twice enlarged, once by extending it in the rear and adding a fourth story, and a second time by occupying one of the adjoining houses. Then in 1909 the Board of Trustees, consisting of Drs. William H. Welch, Miles F. Porter, M. L. Harris, W. W. Grant, Philip Marvel, W. R. Townsend, Philip Mills Jones and W. T. Sarles (the remaining member, Dr. T. J. Happel, died before the Board could officially present its report), recommended at the Atlantic City session of 1909 the erection of a new building to cost approximately \$200,000. The money, in the shape of bonds, certificates of deposit in banks and cash, was on hand for the enterprise. The Reference Committee, which included Alexander R. Craig, Donald Campbell, E. D. Martin, J. W. Pettit and D. S. Fairchild, recommended the adoption of the report of the Board of Trustees. In March 1910, construction of the building was begun. It was of steel, brick and hollow tile, six stories with high basement, and occupied the corner of Dearborn Street and Grand Avenue, as shown in the accompanying illustration. To this building was given the number 535 North Dearborn Street, a number now famous throughout the medical world because of the accomplishments of the Association that it represents.

Fig. 3.—Eight-story and penthouse stone structure now headquarters of the Association.

The circulation of *THE JOURNAL* continued to grow, and the collateral printing and publishing business developed amazingly. It soon became apparent that the building must be completed.

The World War temporarily delayed the matter, but in May 1922 the Board authorized the completion of the building to include the central doorway and a six-story structure capable of expansion if additional stories should become necessary. It was little thought at the time that

Fig. 4.—Modernistic entrance of new building.

the rapid expansion of the next few years would demand the new stories promptly. Yet by 1935 conditions in the headquarters office were so overcrowded that a special committee of the Board of Trustees was appointed to look into the possibilities of finding a new site and of erecting a new building or of working out some other plan for expansion. The architects of the Association were called into consultation, and the recommendation was adopted for the development of two additional stories with a penthouse. The advice that quantities of stone might be purchased at an exceedingly favorable price having been given to the Board of Trustees, they recommended a new stone exterior for the building and redecoration of the interior so as to modernize the entire structure. This series of operations, just completed, has yielded the monumental building shown in the new illustration—a structure which has aroused the admiration of architects all over the country and which has become the subject of special articles in various architectural magazines.

In subsequent articles, the interior of the building and the various departments will be pictured and described. *(To be continued)*

## Rural Medical Service

Are rural sections of the United States suffering from a lack of available medical service? If so, where are they and what are the conditions responsible for such deficiencies?

The Bureau of Medical Economics of the American Medical Association, with the assis-

tance of the state medical associations, has undertaken an investigation to obtain the facts needed to answer these questions. The first step was to locate the counties with the largest population per physician. While making all possible allowance for the fact that a county is by no means a social or medical unit, it is the unit of nearly all available statistical compila-

1930 census for population figures.

tions. It is also recognized that the ratio of population to physician is far from being an exact measure of medical service available. The most that can be claimed for such a ratio is that it is an indication of the extent to which such services are available.

According to the Medical Directory for 1934 there were sixteen counties in the United States

having no physicians; in 1936 there were nineteen. Since nearly all these counties were in isolated districts having an average population of about one person per square mile they do not present any general or typical problem. They are therefore considered only incidentally in this discussion. There were 297 counties located in thirty states in 1934 in which the population was 2,000 or more per physician. It is not assumed that this arbitrary figure necessarily marks the point at which medical service is insufficient but only that if any insufficiency does exist it might be found in the localities included in these counties. There was a total of 1,657 physicians in such counties in 1934 and 1,753 in 1936. This was an increase of 5 per cent in the number of

\* This column shows the number of counties having more than 2,000 population per physician in 1918 (table 1) which had the same ratio in 1936.

physicians in these counties during a period when the increase in the total number of physicians in the United States was but a little over 2 per cent.

A study was made of the social and economic conditions in these 297 counties which might furnish some information on the question of the extent and availability of medical service. This included the assembly of information concerning income, retail sales, farm values, relief granted, and such vital statistics as could be found.

Because the county is not always a practical unit for the supply of medical services, the general hospital facilities in the adjoining counties were compiled with the rate of bed occupancy. The quantity of such facilities and

the degree of their use gives a rough idea of the extent to which physicians in neighboring counties are available.

These facts have been assembled for all states containing four or more counties with 2,000 or more population per physician. Such a factual foundation is a first step to any intelligent consideration of the question of the existence of localities without adequate medical service. Because of the wide local variations in the problems presented in different sections, the conditions in each state will first be presented to form a factual foundation for a general discussion of rural medical service, which will follow the discussion of individual states.

#### ALABAMA

There are sixteen counties in Alabama in which, according to the 1934 Medical Directory, there were 2,000 or more population per physician. In the next two years the number of physicians in these counties increased from 180 to 181. This increase and a redistribution in several localities reduced the number of persons per physician to less than 2,000 in two of the sixteen counties. Every one of the sixteen counties is in what the Federal Emergency Relief Administration designates as the "Eastern Cotton Problem Area."<sup>1</sup>

Cotton is raised in this area under the "share cropper" or tenant system, concerning which the report<sup>1</sup> says (p.22) "Obviously, the system was merely a variation of the old slave relationship and kept the cropper on the margin of economic existence." Between 1910 and 1916 this area was invaded by the boll weevil, which caused a reduction in the amount of cotton raised and still further lowered the average standard of living. The United States Census of Agriculture for 1935 indicates that the depression is producing another important change in this situation. All these sixteen counties have shown a tendency, since 1930, toward a more diversified farming system. The amount of cotton raised has decreased while corn, hay and other general purpose crops and the amount of livestock have increased.

All the information available indicates that by every standard that can be applied the economic condition of the population is below the average for the state. While the average per capita retail sales for the state is \$95 there is only one of the sixteen counties studied in which the per capita is as high as \$80. The median is between \$48 and \$50, with the lowest \$33 per capita. In the whole state 7.7 persons per thousand made an income tax return. In these sixteen counties the highest number per thousand is 3.8, the lowest 0.5.

The average value per farm for the entire state is \$1,347 and the value per acre is \$18.73.

1. Federal Emergency Relief Administration Division of Research, Statistics and Finance, 1935, pp. 20-23.

This is much below the average for the whole United States, yet in only four of these counties does the value per farm reach the state average. In one county it is \$1,987 per farm and \$36.81 per acre. The median is between \$14.65 and \$14.69 per acre, and the value per farm centers around a little over \$1,000.

Resources are not available within these counties with which to maintain on a self-sustaining basis a decent standard of life as to housing, food, clothing or other necessities of life, including medical service.

Manifestly, the county is not a social or medical unit. If one is to determine the extent of medical facilities available it is necessary to include a wider area. These counties do not make up a contiguous group although they are located in the sections of the state with the poorest farming land and other economic disabilities. All of them have adjoining counties in which, by standards commonly accepted, there appear to be adequate medical facilities. Only one of the sixteen counties has a hospital. This hospital has twenty beds with an average occupancy of ten patients. The counties adjoining the sixteen counties studied have seventy-three hospitals, including duplications where one county adjoins more than one of the sixteen counties. These seventy-three hospitals have 7,851 beds and had an average patient occupancy in 1935 of 4,873, almost exactly a 62 per cent occupancy.<sup>2</sup>

Of the 181 physicians in these sixteen counties there were but twenty-three less than 40 years of age in 1934, and there were twenty-six under that age in 1936. The average age in rural communities has always been greater than in the cities.<sup>3</sup> While 79 per cent of all the physicians in the state of Alabama were under 60 years of age in 1934, only 58 per cent of those in these sixteen counties are below this age. This would seem to indicate that while younger physicians are entering these counties the age of the majority is still much above the average for the state.

Death rates by counties are notoriously unreliable. Deaths are reported in the locality where they took place and not where the deceased had made his home. Moreover, it is quite probable that statistics will be less accurate in localities such as are being studied than in other communities. Yet, since the death rate is one of the best tests of the efficiency of medical service it may be worth while to note the fact that the recorded rate is actually lower in the majority of these counties than in the state as a whole. The death rate in 1933 for the state of Alabama was 10 per thousand for the entire population; 8.4 for the white and 13.1 for the Negro population. A better comparison is probably that

2. Alabama Hospitals Registered by the American Medical Association, J. A. M. A. 106:798 (March 7) 1936.

3. Distribution of Physicians in the United States (Revised), Bureau of Medical Economics, American Medical Association, Chicago, 1936, pp. 56-57, 60-61.

between the death rate in the rural districts of the state, which is 8.9 per thousand for the total population; 7.4 for the white and 11.6 for the Negro. There are only six out of the sixteen counties where the death rate is as high as that for the entire rural communities of the state.

So far as these figures have any value, they would seem to indicate that there is no striking lack of medical service in these counties.

#### ARKANSAS

Only four counties in Arkansas in 1934 had more than 2,000 population per physician. One of these is so close to Memphis, Tenn., as to be able to make use of its ample medical facilities. Moreover, in 1936 an additional physician moved into this county, which reduced the number of persons per physician to less than 2,000. For these reasons the discussion will be confined almost exclusively to the three additional counties. Two of these counties are in the "Eastern Cotton Problem Area"; the other is in the "Applacian-Ozark Area," another "problem area." The cotton counties are in localities where the "share cropper" problem has been so acute as to attract national attention in recent years.

The average retail sales per capita for the state of Arkansas amounts to \$97. In these three counties it is only \$52, \$37 and \$25 per capita annually. This is a rough measure of the "spendable income" and is manifestly too small to permit of any system of sickness insurance, since the estimates of the cost of good medical service, under such systems, vary between \$25 and \$30 per person annually.

The average value per farm for the state of Arkansas is \$1,486. For these counties the value is respectively \$1,003, \$1,050 and \$755. The average value per acre for the state is \$21.20 and for these three counties it is \$23.00, \$10.62 and \$8.59.

The total population of these three counties in 1930 was 39,690, and of these an average of 6,605 were on relief in the year ended June 1, 1935.

In the adjoining counties there are six hospitals with 635 beds in which the average occupancy in 1935 was 251, or 39 per cent. The other two counties have no hospitals in adjoining counties.

In 1934 there were twenty out of thirty-five physicians, whose ages can be determined, who were under 60 years of age. In 1936 this had increased to twenty-two out of thirty-six physicians, but it still shows a large percentage of physicians over 60 years of age as compared with the rural districts throughout the country.

The death rate for the state of Arkansas in 1933 was 8.9 per thousand, the rate for white persons being 8.3 and for Negroes 10.5. In these three counties the rate for the total population was respectively 7.3, 4.2 and 8.3.

#### FLORIDA

In the thirteen Florida counties with more than 2,000 population per physician, nearly all the standards of economic conditions are below the general level of the state as a whole. The counties themselves are located principally in the northern section of the state, where the soil is least productive and where the income from tourists is lowest. Two counties are in the Everglades, the other region of least satisfactory industrial conditions. The state Planning Board has recommended the complete withdrawal of seven of these counties from "arable land" districts; the partial withdrawal of three additional counties is also recommended, and one is included in a forest preserve.

The average retail sales per capita for the state of Florida is \$197. The average for nine of the thirteen counties in 1933 was less than \$100 and in four counties slightly more than \$100. In the state as a whole, 20.8 persons out of a thousand made a federal income tax return in 1933. There were but two of these thirteen counties where the number making such a return exceeded 7 per thousand. The mean of the thirteen counties is slightly above 3 per thousand.

The average value per farm for land and buildings in Florida was \$4,407 in 1933. The average value per acre was \$53.08. Only one of the thirteen counties reached this average. Only two of the remaining counties had a total value per farm as high as \$2,000 and only three counties had a value per acre as high as \$20. In four counties the value per acre was less than \$10.

Many of these counties have an extremely scanty population. The average population per square mile for the state is 26.8; only three of the thirteen counties reach this average, while there are seven in which the population per square mile is 9 or less. These facts suggest that in the majority of these counties it is impossible under present conditions for the existing population to make a living. As was mentioned before, this is also the opinion of the State Planning Board.

Neighboring counties had within a distance of 50 miles thirty-four hospitals with 2,633 beds. Of these only 1,433, or 54 per cent, were occupied in 1935. All these thirteen counties are rather small in area. It would appear that, even considering unfortunate economic conditions, medical services are available to a much greater extent than the fundamental necessities such as food, clothing and shelter.

The average age of physicians in sixteen states and the District of Columbia in 1933 shows that 20.26 per cent were over 60 years of age.<sup>4</sup> In the eleven counties of Florida in 1934, 25 per cent of the physicians were 60 years of age or

4. Distribution of Physicians in the United States, Bureau of Medical Economics, American Medical Association, Chicago, 1935, pp. 62-63.

older; in 1936, 31 per cent of the physicians were 60 or more years of age. It is significant that four physicians moved into these communities between 1934 and 1936 and thereby reduced the number of counties having a population of more than 2,000 per physician from thirteen to ten.

In 1933 the death rate for the state of Florida was 12.1 per thousand; 10.5 per thousand for the white and 15.9 per thousand for the Negro population. The rate in the rural districts was 9.4 per thousand for the total population; 8 per

thousand for whites and 12.4 per thousand for Negroes. In only two of these thirteen counties was the death rate higher than the average for the state. In nine the death rate was lower than for the average of other rural communities in the state. Without claiming any high degree of accuracy for these figures, the fact that they are uniformly below the state average would seem to indicate that there is not a sufficient lack of medical service to increase mortality.

(To be continued)

## Official Notes

### RADIO BROADCASTS

The American Medical Association and the National Broadcasting Company are presenting the second series of dramatized health broadcasts under the title *Your Health*. The first broadcast in the new series, the thirty-second dramatized cooperative broadcast under the title *Your Health*, was given October 13. The theme for 1936-1937 differs slightly from the topic in the first series, which was "medical emergencies and how they are met." The new series is built around the central idea that "100,000 American physicians in great cities and tiny villages, who are members of the American Medical Association and of county and state medical societies, stand ready, day and night, to serve American people in sickness and in health."

The program is broadcast on the Blue network instead of on the Red network, as originally announced.

The topics are announced monthly in advance in *Hygeia*, the Health Magazine, and three weeks in advance in each issue of *THE JOURNAL*. The topics and speakers for the next three programs are:

January 5. "Smog." W. W. Bauer, M.D.

January 12. Winter Health Hazards. W. W. Bauer, M.D.

January 19. Don't Die of Diabetes. Morris Fishbein, M.D.

The time of the broadcast is Tuesday afternoon at 4 o'clock central standard time (5 o'clock eastern time, 3 o'clock mountain time, 2 o'clock Pacific time).

### COMMITTEE ON AIR CONDITIONING

The Committee on Air Conditioning, appointed by the Board of Trustees, including Drs. Carey P. McCord, Prof. C. P. Yaglou, Dr. Emery Hayhurst, Dr. Henry Williams and Dr. William F. Petersen, held a meeting at the headquarters office of the American Medical Association on November 6 for the purpose of organization and to outline a program of study and investigation. This is a committee of the House of Delegates and will render its report to the House at the next Annual Session.

### GRANTS FOR RESEARCH

Applications Invited for Aid in Research on Clinical Problems

The Committee on Scientific Research of the American Medical Association invites applications for grants of money to aid in research on problems bearing more or less directly on clinical medicine. Preference is given to requests for moderate amounts to meet specific needs. For application forms and further information, address the committee at 535 North Dearborn Street, Chicago.

## Woman's Auxiliary

The Woman's Auxiliary expresses here its appreciation to the Board of Trustees and the officials of the American Medical Association for making available through this new bulletin a medium whereby the Auxiliary may be constantly aware of activities throughout the country.

Mrs. J. P. SIMONDS.

### The Annual Session

Our own officers, including our President, Mrs. Robert E. Fitzgerald, and our President-Elect, Mrs. Augustus S. Keck, are earnestly at work preparing for the forthcoming annual session in Atlantic City. The growing membership and activities of the Woman's Auxiliary are an indication of the increasing usefulness of its service to the medical profession. Our official work is becoming standardized, the groups in various states carrying out similar activities in accord with the plans that have been laid before our advisory committees in the medical profession.

### Pennsylvania

Members of the Auxiliary in Pennsylvania, under the leadership of Mrs. David W. Thomas, have reorganized

for a uniform fiscal year. They announce as their aims for the coming year increased membership, increased contributions to the Medical Benevolence Fund and Health Education. The president is visiting the various Auxiliaries with a view to consolidating these efforts. Health programs have been conducted in several counties, and special entertainments have been given in many communities for increasing the Medical Benevolence Fund.

A typical program is that of the Auxiliary in Lackawanna County, in which during the next six months there will be a joint social event with the medical society, several card parties, receptions for new members, health programs and special outings during the summer months.

In Pennsylvania the *State Medical Journal* regularly provides several pages for the Woman's Auxiliary, so that each branch may make a regular report of activities.

### California

The various branches of the Woman's Auxiliary of the California Medical Association have been developing an exceedingly active year. The Alameda County

Medical Association had in September a luncheon in which plans were developed for improving the Scholarship Fund and in which the members of the Auxiliary heard a statement on the issues in the election and the legislation that would come before the state legislature. The October session was a joint dinner with the medical society of the county.

In Fresno County the November session was devoted to a presentation of a debate on state medicine, given by boys representing local school organizations. The December session was a benefit card party, the funds to be used to provide *Hygeia* for libraries, schools and beauty parlors in Fresno.

#### Iowa

At its fall board meeting the Woman's Auxiliary to the Iowa State Medical Society met in Des Moines under

the presidency of Mrs. C. A. Boice. This auxiliary is conducting an essay contest, for which many prizes will be given. A recommended reading list for members of the Woman's Auxiliary has also been compiled by the Woman's Auxiliary to the Polk County Medical Society.

#### Tennessee

Several branches of the Woman's Auxiliary to the Tennessee State Medical Association have been concerning themselves particularly with education of the members in health topics. The Rutherford County organization has taken as a central topic "Contributions Women Have Made to Medicine," the opening session being devoted to the life of Jane Todd Crawford.

In Nashville, the program for the year will be concerned with health conditions in Nashville and Davidson County.

## Medical Economics Abstracts

### SEDGWICK COUNTY, KANSAS, MEDICAL SERVICE

In 1931 the Sedgwick County Medical Society reorganized and employed an executive secretary. One of the first things undertaken was a study of the costs of medical care and the planning of a method of medical service that would meet the needs of the three groups into which the population naturally divided—the indigent, the low pay and the well-to-do. Meetings were held with the Community Chest, the Chamber of Commerce and other citizens' welfare organizations. The FERA having been abandoned, the responsibility for the care of the indigent sick fell on the county commissioners.

There were three ways in which medical care might be given to people of this class: (1) they might be left to the charity of the private physicians, (2) the county might contract with full time physicians to care for the 35,000 persons on relief, or (3) the social agencies might set up competitive private clinics. In spite of the fact that one or all of these have been the customary methods of meeting this situation in American cities, the objections to them were so great that a fourth alternative was submitted by the county medical society.

A central application bureau, through which all requests for indigent medical care must go, was created. A rotating medical staff for the county hospital and down town outpatient clinic was organized, the members of which served without fees. The county pays a small monthly fee to the medical society. The medical society thereby undertook the conduct of a clinic. Social agencies cooperated in eliminating malingers and competitive clinics. Except where there was a specific need, all other free clinics were eliminated. Every case is investigated by a social worker before admittance to the clinic, and no city or county official can receive medical care at the expense of public funds.

The administration of the entire arrangement, including the medical staff, is directed by an advisory council of the Sedgwick County Medical Society.

Having created and set in operation these two organizations, the committee undertook a study to determine the best methods of organizing a medical service bureau for the low income group. It is proposed that those who wish to take advantage of this service will, after investigation, be assisted in making satisfactory financial arrangements, including installment payments. The local community chest is sharing the cost of maintaining this particular service bureau.

It is believed that the foundations have been laid for a fairly comprehensive handling of the most difficult phases of medical service for these groups.

### MILWAUKEE SERVICE PLAN

After some years of study and favorable action by the membership, the Milwaukee County Medical Society opened the offices for a new medical service plan, Oct. 20, 1936. The pattern already tested in Wayne County, Mich., and a number of other counties is followed quite closely.

There is no disturbance of the professional relationship between doctor and patient. Emphasis is laid on the retention of the family physician. Any person who wishes to take advantage of the service may go to the office of the Milwaukee County Medical Society, where an expert will assist him in making the final arrangements that will be most convenient. The physician and, when necessary, the hospital, laboratory or other services needed will be consulted and methods of payment arranged to fit the resources of the patient. No charge is made to the patient for arranging for his medical care. The medical service is in no sense a collection agency, further than that after the financial arrangements are made payments will be made at the office of the Medical Service. In case any one wishes the help available through the service and is in doubt as to the choice of a physician, he may telephone the service, which will supply him with a list of physicians, from which a selection can be made. It is the beginning policy to avoid any extensive publicity that might too rapidly extend the scope of the service, until experience has thoroughly determined its possibilities.

### EYEGASSES FOR CHILDREN ON RELIEF

Four ophthalmologists have recently been added to the medical staff of the New York Emergency Relief Bureau. It is estimated that approximately 11,000 school children from home relief families are in need of glasses.

A traveling eye clinic has also been instituted which gives relief recipients with eye troubles appointments at conveniently located offices at fixed dates. Approximately 200 pairs of eyeglasses are now being distributed weekly.

The ophthalmologists do not give eye treatments to relief recipients. When such treatments are indicated, patients are referred to an eye clinic.

## Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

### ARKANSAS

**District Meeting.**—The Ninth Councilor District Medical Society met at the Hotel Seville, Harrison, December 1. The speakers were Drs. Francis Walter Carruthers, Little Rock, on "Diagnosis and Treatment of Vascular Diseases of the Extremities"; Sidney J. Wolfermann, Fort Smith, "Early Diagnosis of Intestinal Obstruction"; Melvin E. McCaskill, Little Rock, "Congenital Defects of the Uterus"; Grady W. Reagan, Little Rock, "Principles of Treatment of Gonorrhea," and Charles T. Chamberlain, Fort Smith, "Common Colds."

### CALIFORNIA

**Dr. Porter Returns as Dean.**—Dr. Langley Porter, who retired this year as dean of the University of California Medical School, San Francisco, has returned to the position at the request of President Robert Gordon Sproul. His appointment is effective immediately. He succeeds the late Dr. Williams McKim Marriott, who died shortly after taking over the duties of dean. Dr. Porter has been associated with the University of California since 1918.

**Heart and Tuberculosis Study.**—The California Heart Association has been organized with the following officers: Drs. John C. Ruddock, Los Angeles, president; John J. Sampson, San Francisco, vice president, and Howard F. West, Los Angeles, secretary-treasurer. The Los Angeles County Heart Association has been reorganized as a branch of the state group. It has been announced that a statewide program for the study and prevention of heart and vascular diseases will be undertaken cooperatively by the new California Heart Association and the California Tuberculosis Association. A cooperative program is also under way between the Los Angeles County heart and tuberculosis associations.

**Third Annual Graduate Assembly.**—The Alumni Association of the College of Medical Evangelists presented its third annual graduate assembly in Paulson Hall, Los Angeles, December 6. The following program was offered:

- Dr. Harry E. Alderson, San Francisco, Rhinoscleroma—A California Problem.
- Dr. John MacKenzie Brown, Los Angeles, Sinusitis in Children.
- Dr. Curle Latimer Callander, San Francisco, A New Amputation Through the Thigh at the Knee.
- Dr. James F. Churchill, San Diego, A Discussion of Cardiac Drugs and Their Uses.
- Dr. Harold K. Faber, San Francisco, Prophylaxis of Communicable Diseases.
- Dr. Alvin G. Foord, Pasadena, Laboratory Diagnosis for the General Practitioner.
- Dr. Verne C. Hunt, Los Angeles, Surgical Treatment of Duodenal and Gastric Ulcers.
- Dr. Alexander Ray Irvine, Los Angeles, Problem of the Cross-Eyed Child.
- Dr. William J. Kerr, San Francisco, Obesity and Its Complications.
- Dr. William S. Kiskadden, Los Angeles, Technic of Repair of Skin Defects.
- Dr. Alfred E. Koehler, Santa Barbara, Functional Indigestion.
- Dr. Verne R. Mason, Los Angeles, Hemoglobin.
- Dr. James N. Nichols, Los Angeles, Surgery of the Aged.
- Dr. Eberle Kost Shelton, Santa Barbara, The Thyroid and Pituitary Factors in Growth and Development.
- Dr. Roy E. Thomas, Los Angeles, The Management and Specific Treatment of Lobar Pneumonia.
- Dr. Howard F. West, Los Angeles, Deficiency Disease Conditioned by Gastro-Intestinal Pathology.
- Dr. Montague S. Woolf, San Francisco, The Commoner Surgical Diseases of the Rectum and Anus.
- Dr. Walter M. Dickie, director, state department of public health, Berkeley, Plague.

### COLORADO

**Personal.**—Dr. Fred A. Forney, medical director of the Modern Woodmen Sanatorium, Woodmen, Colo., has been appointed medical director and superintendent, succeeding the late John E. Swanger.

### FLORIDA

**Society News.**—Dr. Erasmus B. Hardee, Vero Beach, was elected president of the Florida East Coast Medical Association, November 14, at its annual meeting in Fort Pierce. Other officers are Drs. Frederick K. Herpel, West Palm Beach, and Frederick J. Waas, Jacksonville, vice presidents, and Elbert McLaury, Hollywood, secretary. The next annual session will be held in Hollywood. The Four County Medical Association

(St. Lucie, Martin, Okeechobee and Indian River counties) acted as host and Dr. Melton D. Council, Fort Pierce, president, was toastmaster.

### GEORGIA

**Pediatric Meeting.**—The fourth annual scientific session of the Georgia Pediatric Society was held in Atlanta, December 10, with the following speakers, among others:

- Dr. Julius H. Hess, Chicago, Present Status of Serum Therapy.
- Dr. John A. Toomey, Cleveland, Fundamental Unknowns in Infectious Diseases.
- Dr. William A. Mulherin, Augusta, Observations on Southern Pediatrics.
- Dr. Henry F. Helmholtz, Rochester, Minn., Use of Mandelic Acid in the Treatment of Urinary Infections.

### ILLINOIS

**Questions Answered by Radio.**—The state department of health has added a question box service to its weekly radio broadcast. The department will undertake to answer or discuss over the air questions of general interest concerning preventive medicine that may be submitted by listeners. Questions may be forwarded direct to the state department of public health at Springfield or to WGN, Chicago.

### Chicago

**Protection of Car for Society Members.**—The Chicago Medical Society through its trustees will pay \$50 for the arrest and conviction of any person forcibly entering or stealing the car of a member, or stealing a grip or instruments therefrom, or holding up a member while engaged in the practice of his profession during 1937. According to the society's bulletin, only one reward will be paid for convictions on combinations of the above offenses committed contemporaneously. A sticker will be given each member on payment of his 1937 dues, to be used for identification by the police department and other law-enforcing officers of Cook County.

### IOWA

**Releases for Newspapers.**—The speakers' bureau of the Iowa State Medical Society inaugurated a program during November whereby weekly articles on medicine and health will be released to the newspapers in the state. The releases are prepared in the central office, approved by a censorship committee of five physicians and then mailed to the newspapers. A similar plan has been carried out in Wisconsin, Minnesota and Illinois.

**State Journal Has New Editor.**—Dr. Lee Forrest Hill, Des Moines, has been appointed editor of the *Journal of the Iowa State Medical Society*, effective January 1. He succeeds Dr. Ralph R. Simmons, who was recently promoted to be medical director of the Equitable Life Insurance Company of Iowa. Dr. Simmons has been identified with the state journal for about thirteen years, the first three of which he served as associate editor. He will continue in the latter capacity.

**Dr. Haygood Deputy Health Commissioner.**—Dr. Marvin F. Haygood, recently medical director of the Georgia emergency relief administration, Atlanta, has been appointed director of local health services for the Iowa State Department of Health. He will have charge of developing district and county health unit programs under the social security act, it is reported. Dr. Haygood will also become deputy health commissioner, succeeding Dr. Frederick J. Swift, who resigned to become superintendent of the Iowa Soldiers Home, Marshalltown. Dr. Haygood was once director of the county health work for the Georgia State Board of Health. He served as city health officer of Knoxville, Tenn., for six years and as superintendent of the Georgia Tuberculosis Sanatorium at Alto, five years.

**Society News.**—Dr. Karl A. Menninger, Topeka, discussed psychologic factors in medicine before the Pottawattamie County Medical Society in Council Bluffs, November 16.—The Poweshiek County Medical Society devoted its meeting in Montezuma, October 13, to a discussion of medical economics; Dr. Joseph L. Ravitts, Montezuma, was the speaker.—Dr. William D. Paul, Iowa City, discussed coronary heart disease before the Washington County Medical Society in Washington, October 26.—At a meeting of the Winneshiek County Medical Society in Decorah, October 13, Dr. Maurice C. Melrose, Independence, spoke on the treatment of varicose veins and ulcer.—Dr. Edward H. Rynearson, Rochester, Minn., addressed the Woodbury County Medical Society in Sioux City, October 19, on recent advances in endocrinology. Dr. Louis M. Rosenthal, Chicago, addressed the society, November 19, on "Recent Advances in the Radiation Treatment of Cancer."

## KENTUCKY

**Society News.**—Dr. John H. J. Upham, Columbus, Ohio, President-Elect of the American Medical Association, addressed the Jefferson County Medical Society, Louisville, December 21. —Dr. Frank M. Stites Jr. addressed the Louisville Society of Physicians and Surgeons, December 17, on "Diseases of Later Life and Their Significance."

**Restoration of Ephraim McDowell's Home.**—At the annual session of the Kentucky State Medical Association in October, the committee on the Ephraim McDowell Memorial reported that the McDowell home in Danville has been purchased and is in the course of restoration as far as possible to the condition it presented at the time of Dr. McDowell's occupancy. Part of the purchase price was donated by the owners. For the remainder and for restoration purposes a WPA grant of \$13,500 was obtained on the condition that the title to the property be vested in the state park commission. A fund of \$10,000 has been raised from individual contributors, principally members of the Kentucky State Medical Association and the Southern Surgical Association, which also has a McDowell Memorial Committee. The committee also reported that the WPA architect has accumulated a collection of literature on Dr. McDowell, which will be placed in the memorial. It has been revealed that a building now being used as a pool room was undoubtedly Dr. McDowell's office and negotiations are under way to obtain it and restore it to its original state. The committee plans to have a bronze statue of the pioneer surgeon placed on the grounds if sufficient funds can be raised. Dr. Irvin Abell, Louisville, is chairman of the McDowell Committee and the members are Drs. Charles A. Vance, Lexington; Louis W. Frank and Arthur T. McCormack, Louisville; John Rice Cowan, Danville, and Carl C. Howard, Glasgow.

## LOUISIANA

**Society News.**—The Orleans Parish Medical Society was addressed, November 23, by Drs. Emmerich von Haam and Charles R. Lafferty on "Etiology of Venereal Lesions"; Eugene B. Vickery, "Some Minor Disorders of the Female Urethra," and Michael E. DeBakey, "Surgical Treatment of Scleroderma."

**The Chaillé Memorial Oration.**—The eleventh Stanford E. Chaillé Memorial Oration of the Orleans Parish Medical Society was presented December 14. Instead of one speaker as formerly, the program this year was given by the following three speakers:

- Dr. Donald C. Balfour, Rochester, Minn., The Etiology and Treatment of Peptic Ulcer.
- Dr. Frederick A. Collier, Ann Arbor, The Administration of Fluid in the Surgical Patient.
- Dr. Arthur W. Allen, Boston, Acute Abdominal Emergencies.

**Dr. Bel Honored.**—A banquet was given in honor of Dr. George S. Bel, professor of medicine, Louisiana State University Medical Center, New Orleans, December 3, in celebration of his recent appointment as director of Charity Hospital. Patients, former patients, city and state officials, and friends attended the dinner. Judge William W. Westerfield presided and speakers included Gov. Richard W. Leche, at whose birth Dr. Bel officiated, Judge Rufus E. Foster, and Drs. W. D. Phillips and Frederick L. Fenno. Dr. Bel is emeritus professor of the theory and practice of medicine and clinical medicine at Tulane University of Louisiana School of Medicine.

**First New Orleans Graduate Assembly.**—The First New Orleans Graduate Medical Assembly will be held March 8-11. Instruction, clinical demonstrations, didactic lectures, round table discussions, and symposiums will make up the program, which will be presented by the following speakers, among others:

- Dr. Ralph M. Waters, professor of anesthesia, University of Wisconsin Medical School, Madison.
- Dr. Albert C. Furstenberg, dean and professor of otolaryngology, University of Michigan Medical School, Ann Arbor.
- Dr. Anthony Bassler, New York.
- Dr. Frank Lynch, professor of obstetrics and gynecology, University of California Medical School, San Francisco.
- Dr. Russell Cecil, professor of clinical medicine, Cornell University Medical College, New York.
- Dr. Lewis J. Pollock, professor of nervous and mental diseases, Northwestern University Medical School, Chicago.
- Dr. Henricus J. Stander, professor of obstetrics and gynecology, Cornell University Medical College, New York.
- Dr. Clifford B. Walker, associate clinical professor of surgery (ophthalmology), University of Southern California School of Medicine, Los Angeles.
- Dr. Robert B. Osgood, John B. and Buckminster Brown professor of orthopedic surgery, emeritus, Harvard University Medical School, Boston.
- Dr. John A. Kolmer, professor of medicine, Temple University School of Medicine, Philadelphia.
- Dr. Julius H. Hess, professor of pediatrics, University of Illinois College of Medicine, Chicago.
- Dr. Rolla E. Dyer, U. S. Public Health Service, Washington, D. C.

Dr. Eugene P. Pendergrass, assistant professor of radiology, University of Pennsylvania School of Medicine, Philadelphia.

Dr. William W. Babcock, professor of surgery and clinical surgery, Temple University School of Medicine, Philadelphia.

Dr. Abernethy Benson Cannon, associate professor of dermatology, Columbia University College of Physicians and Surgeons, New York.

Dr. George Gray Ward, emeritus professor of obstetrics and gynecology, Cornell University Medical College, New York.

Dr. George Morris Piersol, professor of medicine, Medical Chirurgical College, Graduate School of Medicine, University of Pennsylvania, Philadelphia.

Dr. Hugh Trout, Jefferson Hospital, Roanoke, Va.

Dr. Meredith F. Campbell, clinical professor of urology, New York University College of Medicine, New York.

## MARYLAND

**Personal.**—Drs. Arthur M. Shipley, professor of surgery, University of Maryland School of Medicine, and associate professor of surgery, Johns Hopkins University School of Medicine, and Louis P. Hamburger, associate in medicine, Johns Hopkins University School of Medicine, Baltimore, have been appointed consultants to the Baltimore City Health Department. —Elmer V. McCollum, Sc.D., Baltimore, has been appointed a member of the U. S. P. vitamin advisory board, succeeding the late Lafayette B. Mendel, D.Sc. —William E. Woodall, chief disinfectant, Baltimore City Department of Health, recently resigned. He had been associated with the department since Nov. 1, 1902.

**Society News.**—Dr. Rolla E. Dyer, U. S. Public Health Service, discussed "Typhus and Rocky Mountain Spotted Fever" before the Baltimore City Medical Society at its annual meeting December 4. Dr. Morris Fishbein, editor of THE JOURNAL, addressed the society meeting jointly with the Osler Historical Society, December 18, on "Medical Bookplates." Dr. Francis R. Packard, Philadelphia, discussed case reports of Dr. Philip Syng Physick at the Pennsylvania Hospital. —The Allegany-Garrett County Medical Society was recently addressed by Drs. John P. Stump, New York, on "Prevention of Deformities in Arthritis" and George H. Preston, Baltimore, "The Problem of the Care of Mental Cases in Maryland." —At a recent meeting of the Baltimore County Medical Society, Dr. Milton B. Kress, Towson, among others, spoke on "Modern Concepts of Collapse Therapy." —The Frederick County Medical Society was addressed recently by Drs. Cyrus F. Horine, Baltimore, on "Empyema in Children" and George H. Preston, Baltimore, "Relationship of the Family Physician to the State Institutions Caring for the Mentally Ill."

## MASSACHUSETTS

**Society News.**—Dr. Fletcher H. Colby, Boston, was chosen president of the New England Branch of the American Urological Association in Boston, November 12, and Dr. George C. Prather, Boston, secretary. —At a meeting of the Greater Boston Medical Society, December 1, Drs. Jacob Wallace, Gabriel J. Rubin, Harold J. Freedman, Morris Ingall and George Kahn discussed "Abdominal Pain in Infancy and Childhood." —Dr. Edwin B. Astwood, Baltimore, addressed the Harvard Medical Society, December 8, on "The Physiology of the Breast." —At a meeting of the Boston Pathological Society, December 1, Alfred Marshak, Ph.D., spoke on "Chromosome Structure, with Relation to Radiation," and Dr. Shields Warren, "The Effect of Radiation on the Skin."

**Medical Extension Courses.**—The Massachusetts Department of Education and the Massachusetts Society of Mental Hygiene began a series of lectures, November 12, on "Keeping Mentally Fit." With Dr. Henry B. Elkind, Boston, medical director of the state society for mental hygiene as the course leader, the lecturers include:

- Joseph Jastrow, Ph.D., New York, Keeping Mentally Fit, November 12.
- Dr. Douglas A. Thom, Boston, The Child: The Father of the Man, November 19.
- Dr. Milton E. Kirkpatrick, Worcester, Adolescent Problems, December 3.
- Dr. Abraham Myerson, Boston, Civilization and Its Discontents, December 10.
- Dr. Jacob E. Finesinger, Boston, Practical Applications of Mental Hygiene, December 17.
- Dr. Marianna Taylor, Boston, Moodiness and Fatigue, January 7.
- Dr. Moses Ralph Kaufman, Cambridge, Psychoanalysis and Mental Health, January 14.

The lecturer to conclude the series, January 21, has not been announced.

## MICHIGAN

**Personal.**—Dr. Susie Hurst Thompson, formerly of Gary, Ind., has been appointed in charge of district number 2 of the Children's Fund of Michigan, including the counties of Ogemaw, Alcona, Iosco and Oscoda, with headquarters in West Branch. She succeeds Dr. Gladys J. Kleinschmidt, Ann Arbor, who resigned November 1. This work is conducted in cooperation with the state department of health.

**Model Constitution and By-Laws.**—A special committee will be appointed to study the constitution and by-laws of each of the fifty-four county medical societies of Michigan with a view to developing a model set of regulations with principles conforming to the constitution and by-laws of the state medical society. At a recent meeting of the executive committee of the council of the state society, this step was unanimously approved.

**Tribute to Physician.**—Dr. David D. McNaughton, Argyle, was guest of honor at a banquet, November 30, given to celebrate his completion of fifty years in the practice of medicine in Sanilac County. The hosts were Drs. George Evans and Sanford Martin Tweedie, Sandusky, sons of the late Dr. George S. Tweedie, a close friend of Dr. McNaughton. He was president of the Sanilac County Medical Society from January 1925 to October 1927. He is 70 years old.

**Society News.**—Dr. Albert C. Furstenberg, dean and professor of otolaryngology, University of Michigan School of Medicine, Ann Arbor, discussed "Acute Suppurations of the Throat, Mouth and Cervical Region" before the Wayne County Medical Society, December 14, in Detroit. Dr. Roy R. Kracke, professor of pathology, Emory University School of Medicine, Georgia, addressed the society, December 21, on "The Leukopenic Diseases—Their Etiology, Diagnosis and Treatment."—At a meeting of the Jackson County Medical Society in Jackson, November 17, Dr. Edward G. Martin, Detroit, spoke on "Differential Diagnosis of Anorectal Diseases."

**Dr. McLean Honored.**—Dr. Angus McLean, Detroit, was formally presented with the Order of the Crown of Italy, with the degree of commander, at a banquet recently given in his honor. About 500 persons were in attendance, with Dr. James W. Inches as toastmaster. The presentation was made by the Italian consul, Enrico G. Belcredi, and speakers included Mr. Frank Cody, superintendent of the Detroit public schools and president of Wayne University, and Police Commissioner Pickert of Detroit. Dr. McLean was associated with his alma mater, the Detroit College of Medicine and Surgery, now the Wayne University College of Medicine, from 1905 to 1913 as professor of clinical surgery. He served as city physician from 1888 to 1892; quarantine inspector for the Port of Detroit, 1893, became a member of the state board of health in 1905, and, in 1911, a member of the Detroit Board of Health. He is a past president of the Wayne County Medical Society and of the Michigan State Medical Society.

## MINNESOTA

**University News.**—The Center for Continuation Study at the University of Minnesota was dedicated, November 13-14. The building was financed in part by the PWA and contains living quarters and conference rooms, to be used for refresher courses of short duration.

**Congress of Allied Professions.**—Representatives of all professions allied in the delivery of medical care, including nurses, dentists, druggists, hospital executives and members of the bar, will be invited to an all day conference to be a feature of the eighty-fourth annual meeting of the Minnesota State Medical Association, St. Paul, May 3-5. The conference is scheduled for Monday; the speakers will include Dr. Morris Fishbein, editor of *THE JOURNAL*, Chicago; Father Alphonse M. Schwitalla, dean, St. Louis University School of Medicine, St. Louis, and Dr. Maxwell J. Lick, Erie, Pa., president of the Medical Society of the State of Pennsylvania.

## MISSOURI

**New State Health Commissioner.**—Dr. Herman S. Gove, Linn, since 1934 director of the department of child hygiene, state department of health, has been appointed health commissioner of Missouri, succeeding Dr. Elmer T. McGaugh, resigned. Dr. Gove, prior to 1925, was for several years health officer of Osage County. In 1925 he was appointed a member of the state board of health, serving a term of six years, and in 1933 was appointed director of licensure in the office of the state health commissioner. Aged 57, Dr. Gove is a graduate of the Marion-Sims College of Medicine, class of 1901.

**New Anatomical Society.**—The organization of the Kansas City Anatomical Society was announced November 28. Dr. William Byron Black, president of the Kansas City Society of Ophthalmology and Otolaryngology, was elected president. Other officers are Drs. Albert N. B. Lemoine, Kansas City, and Lyman Robert Forgrave, St. Joseph, vice president; Willis

E. Keith, secretary, and Oliver S. Gilliland, treasurer. Monthly meetings will be held by the new society, whose object is to offer postgraduate instruction. For the first three years the society's membership will be restricted to physicians interested in the eye, ear, nose and throat.

**Memorial Meeting to Dr. Marriott.**—A meeting in commemoration of the late Dr. W. McKim Marriott will be held in the auditorium of Washington University School of Medicine, St. Louis, January 3. Speakers will include Chancellor George R. Throop; Dr. Edwards A. Park, professor of medicine, Johns Hopkins University School of Medicine, Baltimore; Dr. Alexis F. Hartmann, professor of pediatrics at Washington, and Philip A. Shaffer, Ph.D., professor of biological chemistry and head of the department, Washington University School of Medicine. At the time of his death, November 11, Dr. Marriott was dean of the University of California Medical School, San Francisco, a position he assumed at the beginning of the school year. He had been dean of Washington University School of Medicine since 1923.

## NEW JERSEY

**Health at Trenton.**—Telegraphic returns to the U. S. Department of Commerce from eighty-six cities with a total population of 37 million for the week ended December 19, indicated that the highest mortality rate (24.8) appeared for Trenton and the rate for the group of cities was 12.9. The rate for Trenton for the corresponding week of 1935 was 18.8 and that for the group of cities was 12.3. The annual rate for the eighty-six cities for the fifty-one weeks of 1936 was 12 as compared with 11.4 for the corresponding period of 1935. Caution should be used in the interpretation of these weekly figures, as they fluctuate widely. The fact that certain cities have a large Negro population or that they are hospital centers for large areas may tend to increase the death rate.

## NEW MEXICO

**Indian Service Meeting.**—Dr. Marshall E. Burgess, Oraibi, Ariz., was elected president of the Indian Service Medical Society at its semiannual meeting in Albuquerque in November; Dr. James C. Hancock, Fort Apache, Ariz., was made secretary. Dr. William L. Lockman, Mescalero, read a paper on Malta fever and Dr. Hancock a paper on treatment of trachoma. The next meeting will be at Phoenix, Ariz., in the spring.

## NEW YORK

**Society News.**—Dr. Edward K. Cravener, Schenectady, addressed the Medical Society of St. Lawrence County, November 19, on diseases of the hip joint in children.—Dr. Philip B. Barton, Amsterdam, discussed bronchoscopy in general medicine before the Medical Society of Fulton County, November 19.—Dr. Frederic E. Elliott, Brooklyn, addressed the Medical Society of the County of Nassau, Mineola, December 15, on "The Threat of Compulsory Health Insurance," and Courtney R. Hall, Ph.D., assistant professor of history at Adelphi College, Garden City, on "Medical History of Long Island."

**Dr. Farrand to Retire from Cornell.**—Dr. Livingston Farrand, president of Cornell University, Ithaca, since 1921, will retire June 30, it was announced recently. Dr. Farrand, now 69 years old, was graduated from the College of Physicians and Surgeons of Columbia University in 1891 and was instructor in psychology there from 1893 to 1901, adjunct professor of psychology from 1901 to 1903, and professor of anthropology from 1903 to 1914. In the latter year he became president of the University of Colorado and served there until March 1919, when he was made chairman of the central committee of the American Red Cross. He was with the Red Cross until appointed president of Cornell in October 1921. Among his other activities, Dr. Farrand was executive secretary of the National Association for the Study and Prevention of Tuberculosis from 1905 to 1914, editor of the *American Journal of Public Health*, 1912 to 1914, and director of tuberculosis work in France for the International Health Board of the Rockefeller Foundation, 1917-1918. Dr. Farrand has received many honors, including degrees from numerous universities and the decoration of the Legion of Honor of France. His successor at Cornell will be Edmund Ezra Day, Ph.D. (Harvard 1909), director for the social sciences of the Rockefeller Foundation since 1928 and of the General Education Board since 1933. He has contributed frequently to journals of psychology and anthropology.

## New York City

**Etching as a Hobby.**—The fifth annual exhibition of the Haden Etching Club, composed of dentists and physicians who etch as a hobby, was held at the Leonard Clayton Gallery, December 1-12. This year work of the last five years was shown in addition to new plates. Exhibitors included Drs. Leigh H. Hunt, Jacob L. Maybaum, Benjamin F. Morrow, Henry Smith Williams, Jerome Selinger, Harold S. Vaughan and Joseph F. Saphir. Also included in the exhibit was a self portrait of Sir Francis Seymour Haden, famous English surgeon-etcher, lent by the artist's grandson. Dr. Leigh H. Hunt is honorary president of the club; B. W. Weinberger, D.D.S., president, and Charles Berger, D.D.S., secretary.

**Personal.**—John T. Hanks, D.D.S., former director of the division of dentistry in the New York City Department of Hospitals, died suddenly November 17 on a subway train, aged 66. Dr. Hanks was a member of the committee on community dental service of the New York Tuberculosis and Health Association, for several years chairman of the dental supplies division for the American Red Cross in New York, and a member of the economics committee of the American Dental Association. In 1934 Federal Emergency Relief Administrator Harry Hopkins appointed him consultant on dental care for the FERA. Recently he was appointed a member of the World's Fair committee. —Joseph C. Hinsey, Ph.D., formerly professor of anatomy at Stanford University School of Medicine, San Francisco, has been made professor and head of the department of physiology at Cornell University Medical College. Dr. Hinsey succeeds Dr. Herbert S. Gasser, who became director of the Rockefeller Institute for Medical Research in July 1935.

**Lectures on Heart Disease.**—The New York Heart Association, the heart committee of the New York Tuberculosis and Health Association, is sponsoring lectures for practicing physicians on heart disease. The first four have been as follows: Drs. Robert H. Halsey, November 10, "Symptoms and Clinical Examination of the Cardiac Patient"; Clarence E. de la Chapelle, November 24, "X-Ray and Fluoroscopy of the Heart"; Robert L. Levy, December 8, "Clinical Electrocardiography"; Ernst P. Boas, December 22, "Hypertensive Heart Disease and Blood Pressure." The rest of the series will be:

Dr. Edwin P. Maynard Jr., Cardiovascular Syphilis, at the New York Academy of Medicine, January 12.

Dr. Eugene F. Du Bois, The Heart in Thyroid Disease, Cornell University Medical College, January 26.

Dr. Harold E. B. Pardee, Arteriosclerotic Heart Disease, New York Academy of Medicine, February 9 and 23.

Dr. Arthur C. DeGraff, Rheumatic Heart Disease, Bellevue Hospital, March 9 and 23.

Dr. Cary Eggleston, Treatment of Heart Disease, April 13 and 27.

There is no registration charge or admission fee.

**Faculty Appointments at New York Medical College.**—The following faculty appointments, among others, were recently announced by New York Medical College and Flower Hospital:

Drs. Robert S. Bickley and Henry Dawson Furniss, clinical professors of surgery.

Dr. Thomas Drysdale Buchanan, clinical professor of anesthesia.

Dr. Robin Hood, clinical professor of proctology.

Dr. Leon S. Loizeaux, clinical professor of gynecology and obstetrics.

Dr. Thomas Hodge McGavack, formerly of San Francisco, associate professor of medicine.

Drs. Edward J. McCabe and Ferdinand Montgomery Smith, associate clinical professors of surgery.

Drs. Harold E. Clark, Sexton C. Roane and Charles J. Goeller, assistant clinical professors of surgery.

Louis B. Dotti, Ph.D., assistant professor of physiology and biochemistry.

Dr. Edmund H. Hubner, assistant clinical professor of gynecology and obstetrics.

Dr. Guilford Allen Robinson, assistant clinical professor of radiology.

Dr. Paul M. Wood, assistant clinical professor of anesthesia.

Dr. Vincent T. Frankfurth, formerly assistant superintendent of the Michigan Farm Colony for Epileptics, Wahjamega, Mich., was made assistant medical superintendent of the Flower-Fifth Avenue Hospital. Miss Laura R. Logan, formerly director of nursing service at Cook County Hospital, Chicago, has been appointed principal of the school of nursing and director of nursing service at the hospital.

## OHIO

**Society News.**—Dr. Paul B. Magnuson, Chicago, addressed the Montgomery County Medical Society, Dayton, December 4, on "Types and Cases of Arthritis." —Dr. James G. Carr, Chicago, addressed the Stark County Medical Society, Alliance, November 12, on "Treatment of Heart Disease." —Dr. Anthony J. Lanza, New York, addressed the Mahoning County Medical Society, November 17, on "Trends in Medicine." —Dr. William Allen Pusey, Chicago, addressed the Academy of Medicine of Cincinnati, December 8, on "Disease, Gently of the Mind, with Special Reference to the Stimulating Influ-

ence of Skin Disease." At a meeting December 15 the speakers were Dr. Sidney M. McCurdy, Columbus, medical supervisor of the state industrial commission, on "Our Medical Relations with Each Other"; Dr. Roy J. Secrest, Columbus, assistant supervisor, "Compensable Injuries from the Medical Standpoint," and Judge Thomas M. Gregory, chairman of the commission, "Problems Encountered in the Administration of Workmen's Compensation." —Dr. Harve M. Clodfelter, Columbus, addressed the Muskingum County Medical Society at Zanesville, November 4, on "The Anemias and Their Treatment."

## PENNSYLVANIA

**State Tuberculosis Meeting.**—The forty-fifth annual meeting of the Pennsylvania Tuberculosis Society will be held in Philadelphia at the Benjamin Franklin, January 19-20. There will be sessions on health education, the need for additional tuberculosis hospital beds and modern health needs and a medical session. Among the speakers will be Drs. Esmond R. Long, Philadelphia; Jay Arthur Myers, Minneapolis; Robert E. Plunkett, Albany, N. Y.; Kendall Emerson and Harry E. Kleinschmidt, New York.

**Personal.**—Dr. Edgar S. Buyers, Norristown, was recently elected president of the Montgomery County Medical Society after having served as secretary for twenty-one years. It is reported that he was absent only once and that when he was on official business for the society. Dr. Buyers is chairman of the board of trustees of the Medical Society of the State of Pennsylvania. —Dr. Paul C. McAndrew, Scranton, has been appointed medical director of the Lackawanna County Tuberculosis Sanatorium to succeed Dr. Frank R. Wheelock.

## Philadelphia

**Second Postgraduate Institute.**—The Philadelphia County Medical Society announces its second annual Postgraduate Institute to be held at the Bellevue-Stratford, April 12-16. The subject this year will be "Diseases of the Chest and Upper Respiratory Tract."

**Society News.**—Dr. Charles H. deT. Shivers, Atlantic City, N. J., addressed the Philadelphia Urological Society, November 23, on "Newer Methods of Preoperative Study in Prostatic Hypertrophy." —Philip Bard, Ph.D., Baltimore, and Detlev W. Bronk, Ph.D., addressed the Philadelphia Neurological Society, November 27, on "The Significance of the Hypothalamic Representation of the Sympathetic Nervous System" and "The Control of Autonomic Activity and the Role of the Hypothalamus" respectively. At a meeting, December 18, the speakers were Drs. George M. Dorrance, on "Alcoholic Injection of the Gasserian Ganglion"; John Q. Griffith and Wilfred E. Fry, "Subarachnoid Hemorrhage with Special Reference to Papilledema," and Michael M. Scott, "Parietal and Cerebellar Lobe Atrophy Associated with Certain Cases of Multiple Sclerosis."

## Pittsburgh

**Society News.**—Dr. Hugh H. Young, Baltimore, addressed the Allegheny County Medical Society, December 15, on "Medical and Surgical Problems in Diseases of the Prostate." —Speakers at a meeting of the Pittsburgh Pediatric Society, December 11, were Drs. Hyman A. Slesinger, Windber, on "Pneumococcal Peritonitis"; Robert A. Knox, Washington, "Hyperinsulinism," and Ellsmer L. Piper, "A Study of the Initial Weight Loss in the New-Born." —At a meeting of the Pittsburgh Academy of Medicine, December 8, the speakers were Drs. Theodore Diller, on "Sexual Problems Which Confront the Medical Profession"; Alvan W. Sherrill, "Clinical Application of Fever Therapy," and Murray B. Ferderber, "Report of Cases Treated by Fever Therapy."

## WASHINGTON

**Dr. C. A. Smith Honored.**—Dr. Clarence A. Smith, Seattle, editor of *Northwest Medicine* since its establishment in 1903, was the guest of honor at a dinner given by the King County Medical Society at the Rainier Club, November 23. Dr. Robert D. Forbes, president of the King County society, presided and gave a brief review of Dr. Smith's life. Dr. Frederick A. Kiehle, Portland, represented the Oregon State Medical Society with a tribute to Dr. Smith. Mr. Judson Jennings of the Seattle Library and Mr. Charles W. Smith of the library of the University of Washington gave talks of appreciation for Dr. Smith's part in the development of the Seattle Medical Library, which has been one of his major interests. Dr. Arthur C. Crookall, Seattle, president of the Washington State Medical Association, presented a watch on behalf of the assembled group and other friends. Dr. Smith, 75 years old, was graduated from Columbia University College of Physicians and Surgeons in 1887 and went to Seattle shortly afterward.

## GENERAL

**International Conference on Fever Therapy.**—The first International Conference on Fever Therapy will be held at Columbia University College of Physicians and Surgeons, New York, March 29-31. The program is divided into four parts with committees in charge as follows: physiology, pathology and methods of production of fever, Drs. Frank W. Hartman, Detroit, chairman, and Charles A. Doan, Columbus, Ohio, secretary of the committee; miscellaneous diseases treated by fever therapy, Drs. Clarence A. Neymann, Chicago, chairman, and Frank H. Krusen, Rochester, Minn., secretary; syphilis, Drs. Walter M. Simpson, Dayton, Ohio, chairman, and Leland E. Hinsie, New York, secretary; gonorrhea, Drs. Stafford L. Warren, chairman, and Charles M. Carpenter, secretary, both of Rochester, N. Y. Those who wish to participate are requested to communicate with the chairman of the section in which they are interested and manuscripts must be submitted to the chairman before February 1. All who plan to attend are requested to register promptly with the general secretary, Dr. William Bierman, 471 Park Avenue, New York. The registration fee is \$15. Baron Henri de Rothschild, Paris, is general chairman of the conference and Dr. Walter M. Simpson, Dayton, is chairman of the American committee.

**Society News.**—Dr. Edward Stanley Ryerson, Toronto, was elected president of the executive council of Nu Sigma Nu at the annual meeting in New Orleans, November 28. Dr. Stuart Graves, University, Ala., is secretary.—The forty-first annual meeting of the Seaboard Medical Association of Virginia and North Carolina was held at Tarboro, N. C., December 1-3. The guest speakers included Drs. Raymond A. Vonderlehr, U. S. Public Health Service, on "The Hidden Scourge"; Howard A. Patterson, New York, "Present Day Trend in Surgery of the Thyroid Gland"; James P. Hennessy, New York, "The Occipitoposterior Position," and Charles W. Mayo, Rochester, Minn., "Recent Advances in Cholelithic Disease." Dr. Philip St. L. Moncure, Norfolk, Va., was elected president and the following were elected vice presidents: Drs. Robert J. Walker Jr., Tarboro; Frederick C. Rinker, Norfolk, Va.; Thomas M. Watson, Greenville, N. C., and Albert A. Creecy, Newport News. Dr. Clarence Porter Jones, Newport News, was reelected secretary, and Virginia Beach was chosen as next year's meeting place.—The Clinical Orthopedic Society met in Dallas, Texas, October 30-31. Officers elected were Drs. James E. M. Thomson, Lincoln, Neb., president; James A. Dickson, Cleveland, vice president, and H. Earle Conwell, Birmingham, Ala., secretary. The 1937 meeting will be in Chicago.

**Radio Forum on Growth of the Child.**—Future lectures to be given in the radio forum on the growth and development of the child, under the auspices of the National Congress of Parents and Teachers, the American Academy of Pediatrics and the National Broadcasting Company, are as follows:

- Dr. Alexander A. Weech, associate professor of pediatrics, Columbia University College of Physicians and Surgeons, New York, January 6, Energy and Growth.  
Dr. Roy G. Hoskins, research associate in physiology, Harvard University Medical School, Boston, January 13, Our Glands.  
Oscar Riddle, Ph.D., investigator, Station for Experimental Evolution, Carnegie Institution of Washington, Cold Spring Harbor, N. Y., January 20, The Action of Glands on Growth.  
Otto Glasser, Ph.D., Cleveland, director, department of biophysics, Cleveland Clinic Foundation, January 27, Effects of Light, Sun and Other Rays on Growth.  
Edwin C. MacDowell, Sc.D., Cold Spring Harbor, N. Y., investigator, Station for Experimental Evolution, Carnegie Institution of Washington, February 3, Heredity or Environment?  
Dr. Arnold L. Gesell, New Haven, director, Clinic of Child Development, Yale University, February 10, How the Mind Grows in Infancy.  
Walter R. Miles, Ph.D., professor of psychology, Institute of Human Relations, Yale University, February 17, How Children's Minds Grow.  
Walter J. Damrosch, New York, February 24, Importance of Music for Growing Children.  
John E. Anderson, Ph.D., director, Institute of Child Welfare, University of Minnesota, Minneapolis, March 3, Emotional Development in Children.  
Dr. Bert I. Beverly, Chicago, assistant clinical professor of pediatrics, Rush Medical College, March 10, The Connection Between Mind and Body Growth.  
Carleton Washburne, superintendent, public schools, Winnetka, Ill., March 17, Fitting the Course of Study to the Child's Mental Development.  
Frank N. Freeman, Ph.D., professor of educational psychology, University of Chicago, March 24, Education and Mental Growth.  
David B. Dill, Ph.D., associate professor of industrial physiology, Harvard Fatigue Laboratory, March 31, Athletics, Exercise and Fatigue in Growing Children.

The lectures are on the Blue network of the National Broadcasting Company every Wednesday from 4 to 4:30 p. m., Eastern Standard Time.

**"Eye Specialist" Wilkinson Sentenced to Penitentiary.**

—The U. S. Post Office Department announces that Matthew O. Wilkinson, alias Dr. Billingsley, alias Dr. Clark, alias J. E. Clark, was sentenced to four years in the Virginia State Penitentiary following his plea of guilty, Dec. 2-3, in Bedford, Va., to a state charge of swindling Mr. S. B. Hawkins, Moneta, out of \$625. Wilkinson, who was arrested in Milwaukee, August 31, and Harold N. Baxley, alias Jack Baxley, and Curtis Yeager, who were arrested in Pittsburgh, September 4, pleaded guilty to the same charge, the latter two being given five years each in the state penitentiary in Virginia. They had been arrested on charges of fraudulent use of the mails in connection with the collection of checks obtained from their victims in the "eyeswinding racket." According to the Post Office Department, December 11, these men will be tried later on the federal charges. When the authorities in California, where Wilkinson was wanted, were beginning to close in on him, he is said to have gone into other states to "practice." In May of last year the eyesight swindle was perpetrated in Arthur, Ill., by a man calling himself "Dr. Snyder of Tennessee." In 1933, in California, Wilkinson was identified through a photograph by a victim as the "Dr. J. C. Snyder" who had treated him. Elliott Wilkinson, said to be Matthew's brother, was also arrested in the recent round up, but no disposition of his case has yet been reported (THE JOURNAL, December 19, p. 2059).

**Orthopedic Surgeons' Meeting.**—The American Academy of Orthopaedic Surgeons will hold its fifth annual convention at the Hotel Cleveland, Cleveland, Ohio, January 10-14. The program will include clinical demonstrations and symposiums on shoulder disability, osteomyelitis, fractures of the ankle and low back pain. The speakers will include:

- Dr. Merrill C. Mensor, San Francisco, Injuries to the Accessory Processes of the Vertebrae.  
Dr. Charles W. Peabody, Detroit, Tendon Transference—Late Result Study.  
Dr. Henry H. Kessler, Newark, N. J., The Cineplastic Amputation.  
Dr. Charles Leslie Mitchell, Detroit, Phosphatase: Its Clinical Significance.  
Dr. Wingate Todd, Cleveland, The Roentgen Ray in the Assessment of Growth and Health.  
Dr. Frederick C. Kidner, Detroit, Torticollis.  
Dr. Herman C. Schumm, Milwaukee, Schanz Osteotomy for Fracture of the Neck of the Femur.  
Dr. W. Eugene Wolcott, Des Moines, Circulatory Studies and Nutrition of the Head of the Femur.  
Dr. Samuel Kleinberg, New York, The Value of Early Weight Bearing in the Treatment of Fracture of the Neck of the Femur.  
Dr. Paul C. Colonna, New York, Reconstruction Operation for Old, Ununited Fracture of the Femoral Neck.  
Dr. Jose Valls, Buenos Aires, Argentina, New Technic for Nailing Fractures of the Neck of the Femur.  
Dr. Charles B. Huggins, Chicago, Bone Marrow and Its Relation to Orthopedic Surgery.  
Howard B. Lewis, Ph.D., Ann Arbor, Mich., Some Aspects of the Utilization of Sulfur Compounds in Health and Disease.  
Dr. Halford Hallock, New York, Arthroplasty of the Hip Joint: An End Result Study of Seventy-Nine Unselected Cases.  
Dr. Beveridge H. Moore, Chicago, Effect of the Periosteum on the Position of Fracture Fragments.  
Dr. Albert B. Ferguson, New York, Roentgenologic Diagnosis of Tuberculosis of the Joints.  
Dr. Dallas B. Phemister and Cly H. Hatcher, Chicago, Pathology of Hematogenous Osteomyelitis.  
Dr. Edwin F. Cave, Boston, Tuberculosis of the Spine in Children.

There will be five radio broadcasts during the meeting: Drs. Melvin S. Henderson, Rochester, Minn., "The Accomplishments of Orthopedic Surgery"; Edwin W. Ryerson, Chicago, "Physically Handicapped Children and Adults"; Albert H. Freiberg, Cincinnati, "Infantile Paralysis"; Robert B. Osgood, Boston, "Recent Advances in Arthritis," and Willis C. Campbell, Memphis, "The Fracture Situation."

## CANADA

**Personal.**—Dr. Thomas A. Patrick, Yorkton, Sask., received a desk set from his colleagues in the Northern Saskatchewan Medical Association at a meeting recently as a tribute to his long service as a physician, almost fifty years. Dr. Patrick graduated from the University of Western Ontario School of Medicine, London, in 1888 and the University of Manitoba Faculty of Medicine, Winnipeg, 1889.

**University News.**—McGill University, Montreal, recently announced a grant of \$17,000 from the Rockefeller Foundation to cover a three year program of research in genetics and experimental cytology.—The following promotions at the University of Western Ontario, London, were reported in the *Canadian Medical Association Journal*:

- Dr. George H. Stevenson to be professor of psychiatry.  
Dr. William P. Tew, professor of obstetrics and gynecology.  
Dr. Earle M. Watson, professor of pathologic chemistry.  
Dr. Russell A. Waud, professor of pharmacology.  
Dr. David W. Crombie, assistant professor of medicine.  
Dr. Paul M. Andrus, assistant professor of radiology.

#### The Medical Uses of Radium

The report of the Medical Research Council on the medical uses of radium summarizes important recent work. At the Royal Cancer Hospital Dr. W. V. Mayneord has investigated the problem of radium dosage and the conversion of milligram hours into roentgens. The question has not been completely settled but there is general agreement among workers that 8 roentgens represents about the dose of radiation from 1 mg. of radium element screened with 0.55 mm. of platinum at a distance of 1 cm. for one hour.

#### THE CARCINOGENIC ACTION OF SCREENED RADIUM

Screened radium has been shown to be capable of producing the disease for the treatment of which it is most used. This research, by Dr. Joan Ross, is based on a case in which a radium needle, used in the treatment of cancer of the breast, became detached and penetrated the chest wall. Attempts to regain it failed and the patient died three years later from heart failure. At the necropsy the needle was found embedded in the interventricular septum of the heart, and there was in the liver a malignant hemangioma immediately under the site of the needle. The mode of spread of the growth through the liver tissue showed that its point of origin was in the part of the liver nearest the radium needle. This pointed to the conclusion that the presence of the needle so long adjacent to the position of the growth was the cause. Radium tubes 1 cm. long, each containing 0.1 mg. of radium screened with 0.55 mg. of platinum, were inserted into rabbits. These containers represent weak gamma-ray sources, the amount of hard beta-rays passing through being negligible. It was intended to open the peritoneum and anchor the tubes in the liver but this was found to be impracticable. After various trials one tube was placed in the chest wall on the right side close to the liver. Some shifting of the tubes occurred probably soon after insertion. Seven out of nine rabbits experimented on developed cancer in the immediate neighborhood of the tube. Six of the growths appeared at intervals between ninety-seven and 135 weeks, the seventh after 167 weeks. Five of the growths were sarcoma and two squamous-cell carcinoma. In all the cases of sarcoma except one (in which the animal was still alive) there were metastases in the lungs or elsewhere. One of the carcinomas had produced metastases in lymph glands and the lungs; the other did not show any. These experiments demonstrated the important fact that small amounts of highly screened radium acting for a sufficiently long period can produce malignant growths the character of which depends on the nature of the tissue in close proximity to the tube, though not in that immediately proximate.

#### CANCER OF THE BREAST

In cancer of the breast, radical operation is still the most usual treatment whenever practicable. At the Birmingham General Hospital, large and inoperable breast cancers have been treated with full doses of high voltage (200,000) x-rays. In some cases these tumors have been rendered operable from eight to ten weeks later. Microscopic examination of these irradiated breasts has almost invariably shown some islets of cancer cells surrounded by dense fibrous tissue. This raises the question of the advisability of removing such irradiated breasts and clearing out the axillae, even after radiation has caused disappearance of the tumor. At the Marie Curie Hospital, radical surgical removal is carried out whenever prac-

ticable. When radiotherapy is used, preference is given to the low intensity method of Coutard. During the past year smaller daily doses have been given over larger fields, with avoidance as far as possible of marked skin and connective tissue reactions.

#### CANCER OF THE MOUTH

The Aberdeen Royal Infirmary reports that, in carcinoma of the lower lip, radium element was used in twenty-one cases and radon in ten, with complete healing after a single treatment. Both the element and radon were fully screened and used interstitially. The impression has been gained that the early response to the radium treatment of secondary malignant nodes is improving.

Eight patients were treated for carcinoma of the tongue. In five the primary growth disappeared and the tongue healed after a single radium treatment. The radium was fully screened and the method was interstitial. In two cases the healed site was excised seven months after the radium treatment and no malignant cells were found on microscopic examination.

The Birmingham General Hospital reports that there is little difficulty in curing primary growths of the buccal cavity, provided the floor is not extensively involved. Effective treatment of secondaries in the neck is much more difficult. Radiation alone—whether radium or high voltage x-rays—rarely cures. The gland fields are treated by dissection, and as soon as the wound is sufficiently healed treatment by a radium collar or high voltage x-rays follows.

#### Social Insurance Questions

Up to now, every worker who has no dependent children and who earns 21,000 francs (about \$1,000, after devaluation of the franc) is obliged to take out social insurance. The employer pays a monthly premium equal to that paid by the worker. A worker who has two or more dependent children and who earns 25,000 francs must be insured. The government has recently proposed a law according to which these salary limits will be raised, so that a large number of workers not now insured will be obliged to join the social insurance organization. In a letter addressed by its president, Dr. Tissier, to the Federation of Medical Syndicates of France, dated August 6 and published in the September issue of the *Bulletin* of the Syndicate of Physicians of the Department of the Seine, the statement is made that, although the question of raising the limit of obligatory insurance is more of an economic than of a professional character, the extension of social insurance, especially in the region of Paris, to a considerably larger number of workers cannot fail to be of interest to the practitioners of this region. The application of the social insurance law has already affected the practice of medicine seriously and imposed a heavy burden, which the profession has accepted in a most loyal manner. Confronted with the proposed modification of the law, the profession feels itself entitled to claim an application of the law which will permit a physician at least to earn a living; hence the authorities are requested to consider the present plight of the profession in France before raising the limit of obligatory insurance. No one can ignore the loss of time, the vexatious examinations, the abusive investigations to which a practitioner is subjected in connection with the medical control demanded by certain caisses or bureaux which pay the claims for illness of the insured. This is especially true of patients treated by the practitioner at his office or at the home of the insured. These disagreeable encounters between the medical inspectors of the caisses and the practitioners, often taking place in the presence of the patients and tending to cause them to lose confidence in their medical atten-

dant, should in the future be avoided in the case not only of those already insured but also, if the proposed limit is raised, of those in the higher salaried brackets, who are more likely to consult a physician than those in the present lower brackets. The original law of 1930 had given the insured workers and their medical attendants a certain number of guaranties, such as free choice of physicians and the equitable adjustment of indemnities, which has induced the majority of the working class to accept the law. The law as modified in October 1935, which was not passed on by the legislature, added a number of restrictions, which have increased the power of the caisses or disbursing bureaus. The regional boards on which the organized medical profession is represented are seldom summoned to meet with the superior council of the social insurance organizations. The secretary of the federation, in his answer to this letter, stated that most of the abuses to which the local (Seine) organization had directed attention were only in the power of the main social insurance organization and its subsidiaries to correct. As to the higher limit of obligatory insurance, this will not go into effect, as proposed in the recent bill.

#### Discussion of Obligatory Retirement Bill

In the *Concours médical* of October 4 appears an analysis of the ideas of those members of the French chamber of deputies who are sponsors of the proposed Pomaret bill to oblige the members of all the liberal professions to surrender their licenses or diplomas when they have reached the age of 65 years and to retire without any thought of compensation by the government. The bill will come up for debate at the next session (November) of the chamber. In the article by Dr. Paul Boudin referred to, the sponsors of the bill are quoted as saying that "it is necessary to make places for those who wish to earn a living and establish a family. Social security demands the elimination of those who are enfeebled by age, i. e., whose intellectual and physical faculties are diminished as compared to those of younger individuals. Hence every profession should be organized from the corporative standpoint so as to permit all those who need repose to retire. No child should work before the age of 14, or 16, if possible. The public should be protected against quacks in every profession." Boudin comments on this by saying that but little has been done with regard to the last named in France. Such an exclusion of quacks would open up more places for the younger aspirants. The forced retirement law would not go into effect until Jan. 1, 1939, so as to permit the various professional groups to organize a system of pensions without, however, any aid from the government. Boudin heartily endorses the measures aiming to exclude quacks and discourage young men and women from overcrowding the liberal professions, as at present, by means of stricter entrance requirements and closer supervision during their courses in the professional schools. Every physician and dentist in France pays a relatively high tax, termed "patente," for the privilege of practicing. Boudin suggests that instead of this tax being paid to the state, it should be turned into a fund which shall serve as an endowment from which physicians or dentists shall be paid a pension should they choose to retire voluntarily at the age of 65. The various medical syndicates or unions are preparing to fight the Pomaret bill with all the resources at their command.

#### Increase in Cardiovascular Disease

In the June 27 issue of the *Presse médicale* two cardiologists, Lian and Cahana, state that the mortality of cardiovascular disorders is constantly increasing and at present exceeds that of pulmonary tuberculosis and cancer. This is shown in the tabulation of statistics for all of France, per hundred thousand inhabitants.

The principal reason for this increase in cardiovascular mortality is the longer average duration of life, which in the sixteenth century was twenty-one years, rising in 1900 to forty-seven years and in 1920 to fifty-four years. If one studies the statistics of cardiovascular mortality according to age, it is evident that it has increased only in those more than 45 years

#### Mortality in France

	1906	1911	1920	1930
Heart disease .....	120	115	106	139
Cerebral hemorrhage .....	83	86	80	80
Pulmonary tuberculosis ....	380	343	227	197
Cancer .....	114	112	128	130
Respiratory disorders .....	291	265	243	188

of age. The cardiovascular mortality has nearly doubled from 1900 to 1920 and tripled from 1920 to 1929 in persons more than 45 years of age. As the vascular diseases such as hypertension, angina pectoris and other coronary disorders, as well as atheromatosis in its various localizations, appear as a rule after the age of 40, it seems reasonable to conclude that the higher cardiovascular mortality is essentially due to the increased average duration of life. Deaths below the age of 40 represent only 3 per cent of the total number due to cardiovascular disease.

#### VIENNA

(From Our Regular Correspondent)

Oct. 22, 1936.

#### The First Austrian Roentgenologic Congress

The Austrian Society of Roentgenology held its first convention September 4-8 at Vienna. Professor Kienböck presided. The convention was attended by 300 leading roentgenologists from all parts of Europe; 119 prepared individual discussions were submitted and numerous discussions and demonstrations took place. The three principal topics under discussion and the men who introduced them by the reading of special papers were (1) "Roentgen Symptomatology as an Expression of Organic Function," Professor Leb of Graz, (2) "Clinical Practice and Methodology of Roentgen Cinematography," Professor Dessauer (a Jewish refugee from Germany, now residing in Istanbul), and (3) "Principles and Development of Roentgenotherapeutic Irradiation Procedures and Their Biologic Foundations," by Professor Schwarz of Vienna.

Professor Freund, himself the first to apply roentgen rays for therapeutic purposes, said in his introductory address that Vienna may be called the birthplace of roentgenotherapy. Freund recollected in this connection with what difficulty he established the new procedure as a part of the therapeutic armament. Any innovation that represents an advance of science has always at first to fight the battle for recognition. Freund said also that one might point with pride to the fact that Vienna has been the scene of a whole group of important developments in the field of roentgenology: roentgenotherapy, arteriography, pyelography, encephalography and other procedures.

The proceedings of the congress were arranged as follows: (a) Roentgenologic diagnostic methods for disturbances of the brain and spinal cord, the lungs and circulation, the digestive system and its subdivisions, the urinary passage, the female genitalia and the skeletal system. (b) The technic and physics of roentgenography: indirect and direct cinematography, kymography. (c) Roentgenotherapy: single session irradiation, saturation treatment, irradiation with extremely high voltage, distant irradiation, contact therapy. Combinations of therapeutic procedures: radium therapy in combination with roentgenotherapy; operative treatment in conjunction with radiotherapy. Moreover, some thirty papers on miscellaneous subjects were submitted.

Professor Leb of Graz, who spoke on the first principal topic, emphasized that the principal function of roentgenographic diagnostic procedure is the demonstration of anatomic changes within the human organism; with this, however, the possibilities of roentgen examination are by no means exhausted. Observations of the living organism disclose not only purely functional disturbances which often represent a preliminary stage of secondary anatomic disorders but other functional disturbances as well, by which whole pathologic syndromes may be established.

Of interest were papers by Professor Schüller of Vienna on the use of contrast solutions for demonstration of the cerebral cavities and by Löhr of Magdeburg on his own methodical investigation of the cerebral arteries. In the course of four years Löhr examined close to 900 cerebral and cranial lesions and arrived at the conclusion that disturbances of the vascular supply in the central nervous system, which are traumatic in origin, permit of remarkably good roentgen visualizations that are most helpful for prognosis. Professor Dyes of Würzburg, after considerable roentgenographic research on tumors of the brain, was able to make the following observations: In all tumor cases in which the seat is the lower posterior half of the posterior cranial fossa, enlargement of the ventricle is present. If, however, the seat is the upper and frontal half, enlargement of the fourth ventricle will be lacking but the three remaining ventricles will show enlargement. As long as the cerebrospinal fluid can enter the fourth ventricle the latter appears of normal size, and without further ado the seat of the tumor is in its lateral aspect to be determined. If the tumor is situated in the region of the sagittal suture, the upper part of the ventricle on the affected side is compressed. Tumors on the convexity present a similar picture. Tumors situated in the temporal region cause the ventricle of the affected side to appear concavely extended over the neoplasm. Excellent pictures of the respiratory mechanism were exhibited with the kymographion by Weber of Bern.

Schuster and Zdansky, both of Vienna, demonstrated how clearly alterations in the size of the heart following the performance of a single piece of work and different types of respiration may be portrayed by roentgenography.

A good part of the convention was taken up in discussion of the roentgenology of the gastro-intestinal tract. Although the lecture and reports on this topic were extremely interesting, by and large nothing fundamentally new was elucidated. Presser of Vienna discussed gastric tumors; Haas of Budapest, gastric motility; Ratkoczy, also of Budapest, circumstances that influence the gastric tonus. A sensation was produced by the explanations of Dillon of Moscow of the respiratory function of the digestive tract. By his experiments it was determined that man as well as many vertebrate animals and fish is capable of inhaling air into the stomach and intestine. The air is actually inhaled, not swallowed, and it may serve to assist respiratory function in general. Incontestable proof exists that it is possible for the organism to live for a certain time exclusively by means of the air inhaled into the digestive tract. Roentgen examination is therefore the best and most reliable test for the determination of whether a fetus will be born living or dead. In two cases cited by the author, new-born infants shown on necropsy to present complete atelectasis of both lungs had lived and cried, the one for a period of twenty-five minutes, the other for five hours.

Roentgen visualization of the appendix vermiformis and the causes of nonvisualization formed the subject matter of a large number of discussions.

Pape of Vienna gave a discussion of disturbances in the colonic power of locomotion and Werner of Bratislava a perhaps more important talk on the rapid testing of colonic function. By means of irrigoradioscopy supplemented by pneu-

mography, the entire large intestine can be completely visualized within eight hours, thus making it possible for the examination to be concluded within the same day.

The importance of roentgenology in recent years has increased; especially noteworthy are the improved methods of demonstrating the intricate urinary passages. Urography of the process of elimination is a useful procedure for functional testing of the kidney and kidney pelvis, especially as it provides indication or contraindication of operative intervention. The first impetus to the research on renal function by means of roentgen rays began in Vienna, although as early as 1887 the physiology of the pelvis of the kidney was investigated by Israel in Berlin. Later on this type of research came to be carried on in various countries.

Simon of Vienna contributed observations on functional alterations in the urinary tract and in the large intestine during pregnancy. It was established that the gravid uterus not only acts by mechanical compression of the urinary tract and the large intestine but gives rise to physiologic disturbances of function in both regions and these may be both toxic and incretory in nature. The atonic and congested state of the organs usually disappears completely subsequent to the pregnancy.

Roentgen cinematography may be said to have aroused greater interest than any other subject before the congress. Janker of Bonn and Reynolds of London, in two lectures on cinematography, differentiated direct and indirect cinematography and concerned themselves with the last-named method. Its principle is the photographing of the fluoroscopic appearance; it is possible to take from twenty-five to fifty pictures a second by means of modern apparatus. Occasionally a rate of as many as 100 pictures a second may be attained. If the direct method is used the size of the single picture corresponds to any of the usual roentgenograms. Consequently the number of pictures in a second and the length of the film are greatly restricted, transportation is rendered much more difficult and the expense is great. By the indirect method one is certain to obtain quickly produced inexpensive and excellent pictures for the study of organic function. It was first used by Reynolds in London in 1920-1921 but at that time presented great difficulties, owing to the imperfection of the technic. As the picture may now be taken speedily and the period of exposure is brief, the procedure is now completely without danger to the patient. Both Janker and Reynolds exhibited truly marvelous pictures before the congress. Especially worthy of mention were the visualizations of cardiac movement, of the acts of swallowing and of speaking, of an embolism artificially produced in animal experimentation, of gastric activity, and of the movements of the larynx and tongue in speaking and singing—in the last named the sound of the voice was reproduced.

The direct method was demonstrated by Van de Maele of Brussels. It permits of a rate of some eight pictures a second and the production of excellent individual pictures. It permits furthermore of a close study of the details of motility in various organs.

Kymography too enlisted the interest of the delegates. It was discussed by Stumpf of Munich.

The discussions of roentgenotherapeutic questions formed the high point of the transactions. Prof. Gottwald Schwarz of Vienna outlined the historical development of this branch. He described the establishment of the generally accepted roentgenometric unit, the roentgen, which was proposed by Villard of Paris in 1908 but first adopted as an international unit twenty years later. Roentgenotherapy has been materially improved in recent years, by Coutard of Paris in particular.

Latterly the controverted question has been the relative merits of the single session method. There is also rivalry between

the fractionated and protracted fractionated methods of irradiation. Evaluations of distance irradiation and of contact therapy were also attempted by the congress.

Wintz of Erlangen advocated single irradiation. Young, rapidly growing cells (such as carcinoma cells) are quickly destroyed by large doses. Irradiation by a series of doses decreases the radioactivity of tumors. Application of even the smallest doses may cause a tumor to become radiorefractive. As a rule the healthy cells in the vicinity of a tumor show themselves more capable of resisting the roentgen rays. Saturation therapy was discussed by Holfelder of Frankfurt. The effect of roentgen rays on a malignant growth is the stronger as the cancer cells are destroyed and the normal cells of the organism protected. This eventuates if the topographic trend of the tumor seat is exactly determined, the overlapping tissue layers delimited by means of a maximal compression and the tumor, so to speak, directly hit. Large doses are at first applied (full tolerance dose), followed by lesser doses for from four to eight weeks.

Coutard of Paris described the roentgen treatment of carcinoma by fractionated protracted daily irradiation and by irradiation in periodic series. This method has made possible the first permanent roentgenotherapeutic cures of carcinoma. The method is basic, dosimetric and quantitative. Its fundamental principle is the amount of the total dose and its physical distribution in space, irrespective of whether the daily dosage is strong or weak. Results are satisfactory only if the carcinoma is scarcely differentiated and infiltration has not yet set in and if the cells exhibit a considerable radiosensitivity that remains fairly constant during the treatment. The total dosage requisite for permanent cure did not as a rule differ greatly, no matter what the distribution. The dosages were from 6,000 to 8,000 roentgens for the larynx, from 7,000 to 8,500 for the pharynx and from 8,000 to 9,000 for the tonsils. The daily dose was around 500 roentgens in the shorter treatments and from 300 to 700 in the serial irradiation. The area of exposure varied from 50 to 125 sq. cm. It was interesting to note that if the total is greatly increased (to from 10,000 to 12,000 roentgens) the only result was deterioration and this was irrespective of the distribution of the application in point of time.

Schinz of Zurich, who spoke on the same topic, has customarily administered the simple fractionated irradiation when, because of the condition of the tumor, he could hope to achieve only a palliative effect. He resorted to the protracted fractionated procedure if the end result anticipated was not merely freedom from symptoms but permanent cure. When employing the first method he administered 1,500 roentgens within five days' time; in following the second method he administered from 4,000 to 15,000 roentgens, the amount depending on the seat of the tumor. Schinz, like Coutard, exhibited statistics on the successes and failures that he had experienced. Of interest are the data on mammary carcinoma. In the operable cases a protracted fractionated preliminary irradiation and a fractionated after-irradiation were administered, whereas in the inoperable cases three irradiations lasting fifty minutes each were administered every second day until a total dosage of 4,000 roentgens had been given, this requiring in all about fourteen days.

Pulmonary carcinoma was discussed by Popovic of Zagreb. In 30 per cent of seventy cases (sixty-eight men, two women, aged from 19 to 70) improvement, both subjective and objective, was obtained, but only two of the patients could be saved. Sgalitzer of Vienna discussed the methods of tumor irradiation in the central nervous system. His first choice was the fractionated method, by which, he said, severe manifestations were avoided. Roentgen treatment of cerebral disorders is best directed from several points of attack; extremely favorable

results have been obtained from the use of this procedure in hydrocephalus. In brain tumor cases also, irradiation from four or five points of attack is beneficial. Whether the cranium is open or closed is an important consideration in irradiation. Radiotherapy is contraindicated if increased compression of the brain is present, excepting in cases of hypophyseal tumor. The optimal end result in brain tumors is anticipated from operation followed by roentgen irradiation. Postoperative irradiation acts favorably in glioma and sarcoma cases in which it has been impossible to effect a radical intervention.

Gunsett of Strasbourg spoke on irradiation with tension as high as 600 kilovolts. This method is chiefly suitable for deeply situated carcinoma. Hard rays should be used. The speaker has administered from 3,500 to 4,000 roentgens in from four to five weeks with a fair measure of success. E. Maier of Vienna spoke on distant treatment with radium. In this type of therapy the "r"-afflux applied per minute is minimal in proportion to the roentgen "r"-afflux. It represents but a fraction of the last-named type of energy and therefore distant irradiation with radium cannot be replaced by roentgen irradiation.

Schäfer of Greifswald discussed the use of contact therapy in gynecologic cases. This method has its advantages: the skin is completely protected by the introduction of certain tubes into the bodily cavities and it is possible to irradiate the parametrium with powerful doses; at the same time healthy tissue is completely protected by filters. Schäfer used irradiation in fifty-six cases of carcinoma of the female genitalia, 38 per cent of which were cases of inoperable carcinoma of the cervix uteri. The primary results were excellent; a check up showed twenty of the cervical cases to be negative, and only one case showed deterioration. The period of observation has been too short to permit conjecture as to end results. It may be said, however, that cases in which marked favorable effect is lacking undergo further deterioration.

Chaoul of Berlin discussed the method of close roentgen irradiation that bears his name. This method was used with satisfactory results in treating 307 patients who presented directly accessible cancerous growths. Patients were submitted to rays of the most promising strength (usually from 6,000 to 10,000 roentgens per field); the administration of the dosage was distributed over several weeks. Melchart of Vienna emphasized that the future method of combating cancer will be the combination of surgery with roentgen rays and at the same time with radium. Wessely and E. G. Mayer, both of Vienna, discussed the present attitude toward treatment of malignant tumors of the upper respiratory and digestive tracts. In very severe cases irradiation should be introduced first and surgical intervention later; frequently the procedure must be reversed in order that the tumor may receive direct irradiation; this would be done in carcinoma of the accessory nasal cavities. Carcinoma of the inner larynx and of the pharynx with metastases in the glands, conditions in which extensive operative intervention was formerly indicated, are now, following the Coutard method, only irradiated.

Radon was discussed as a separate topic by several research scholars, among whom were Happel of Hamburg, Uhlmann of Istanbul and Wasserburger of Vienna. Among disease conditions that react well to this type of therapy are exophthalmic goiter, lymphangiomas, keloids, wounds that tend to heal imperfectly and small epitheliomas.

The report of Ziedses des Plantes of Utrecht created something of a sensation. It dealt with serioscopy, a technic that makes possible by means of multiple exposures the visualization of the body in a whole series of parallel planes, each of which may be considered separately. Among other independent discussions were those by Windholz of Vienna on roentgenotherapy of tumors and hyperplasias of the reticulo-

endothelial system (leukemia, xanthomatosis, blastomatoïd alterations). All these conditions were favorably influenced by roentgen and radium irradiation.

The paper of Freund of Vienna on the problem of occupational injuries from irradiation has yet to be mentioned. Prolonged exposure to roentgen rays produces a condition of general debility, best manifested in the morphologic hemograms. Leukocytes decrease permanently to around 5,000; the whole picture of chronic roentgen intoxication is quite like benzene intoxication as determined by the American Benzene Commission. Therapeutic measures consist of exposure to natural or artificial sun rays of all wavelengths, fresh air, gymnastics, and a regimen of unboiled milk, liver and bone marrow. In desperate cases blood transfusion together with the extirpation of the spleen is recommended. The best therapeutic measure, however, is removal of the patient from the injurious occupational surroundings.

### AUSTRALIA

(From Our Regular Correspondent)

Nov. 15, 1936.

#### A Commission to Study Hospital Lotteries

The government of South Australia appointed a royal commission to inquire whether it is desirable to institute lotteries in South Australia for the purpose of raising funds to assist in the finance of hospitals and other charitable institutions. The commission took evidence in the different states of the commonwealth and had special statistical information about lotteries of Great Britain, Ireland, France, the United States and Canada. The commission expressed itself in its report as being not unduly influenced by the religious or ethical aspect. It says it would not have felt justified in coming to its conclusion or objecting to the lottery system on the ground of ethical objection, if on other grounds it had been found desirable. There is a real difference in principle between a government on the one hand taxing private betting or other private activities of the people and on the other hand introducing a lottery for the purpose of raising money for one of its essential social services. In the former case the government takes no part in the promotion of the activities on which the tax is levied. In the case of a lottery, parliament either directly or through a department established by it promotes the lottery for the purpose of profit and takes an active part in inducing people to subscribe to it. No Australian government urges people by advertisement to bet on horse races in order that more revenue may be obtained from betting or to go to the pictures so that the amusement tax revenue may be increased, but when there are lotteries the public is definitely encouraged to do so.

The commission was much impressed in the course of its investigations by what appeared to be the political repercussions of lotteries either conducted by governments or under a government license. The commission gained the definite impression that lotteries conducted on the lines of those of New South Wales, Queensland and Tasmania tend to become the masters rather than the servants of the government that "controls" them. The commission considered that the state of affairs tends to demoralize governments. After full and careful investigation the commission satisfied itself that the lottery does not and cannot solve the hospital finance problem. Even in Ireland the immense Irish sweep has not relieved the government or the local authorities of their hospital obligations, and in Western Australia and in Queensland lotteries have not helped the government to any material extent. The existence of lotteries in four of the six Australian states, and the seeming benefits derived from them, give an impression that a lottery is desirable. After thorough investigation, however, the commission is satisfied that these benefits are more superficial than real.

It may appear difficult to understand why it is that, with all the revenue that lotteries bring in, the government or local

authorities do not secure corresponding relief. There are several contributing factors to this position: 1. The people of Australia are becoming more and more hospital minded, which means an increasing demand for accommodation. 2. The existence of a lottery tends to create in the people a demand as of right for a much higher standard of hospital buildings and equipment, and for more hospitals. 3. The practice has been generally to use lottery moneys for capital expenditure and therefore the cost of maintenance necessarily increases. 4. The existence of a lottery tends to decrease the voluntary contributions for hospital and charitable purposes, and this factor is greatly accentuated when there is a rate or tax for hospitals as well. 5. Where charities are associated with lotteries, the charitable institutions set up higher standards. 6. It may be that one of the reasons why lottery moneys are spent in the manner in which they are is that such expenditure provides an excellent advertisement for the lottery. For these reasons the commission found that the establishment of a lottery will not materially relieve the government or the local governing authorities of their burdens for hospitals or charities. In fact, because of the higher standard that is built up through the expenditure of lottery moneys as capital the ultimate burden is likely to be increased by the existence of a lottery.

Everywhere says the report there is a tendency to increase the prizes and especially the first prize; and everywhere the lottery is an exploitation of the gullibility of the public and the widespread gambling instinct. In fact, so deep seated has this legalized form of gambling become that it is doubtful whether any government would dare to introduce legislation to abolish these lotteries. The commission concluded that a lottery as a form of hospital finance provides an unstable method that is demoralizing to the government, distinctly injurious to traders and detrimental in the end to the poorer sections of the community, who contribute the bulk of the receipts. If the people who buy lottery tickets can easily afford the money, they can afford to pay their share of the direct taxation necessary to support hospitals. If they cannot afford the money, the state should not take their money. From the establishment of the "golden casket" in Queensland nearly twenty years ago the total receipts amounted to £12,000,000, the prize money amounted to £7,000,000 and the sum paid to hospitals and charities after payment of expenses was £3,000,000. These figures confirm the commission in its belief that the lottery does not and cannot solve the hospital finance problem and consequently it was recommended that the practice should not be permitted in South Australia.

### Marriages

ALEXANDER C. LEONARDO, Washington, D. C., to Miss Alleen L. Bingham of Greensboro, N. C., Sept. 15, 1936.

LAYMAN R. HARRISON, Long Island, N. Y., to Miss Claire C. Colligan of Morristown, N. J., Oct. 3, 1936.

JOHN WATTS FARTHING, Rochester, Minn., to Miss Esther Constance Tasa of Northfield, Sept. 26, 1936.

GLENN GREY PERRY to Miss Agnes Adelaide Williamson, both of High Point, N. C., in October 1936.

WILLIAM DEWEY HALL, Raleigh, N. C., to Miss Sue Ruth Hutto of Gaston, S. C., Oct. 17, 1936.

CRAWFORD DARY DUNHAM, New York, to Miss Margaret Todd of Butler, N. J., Oct. 17, 1936.

JOHN LOUDEN HILLHOUSE to Miss Virginia Jacobs, both of Birmingham, Ala., Oct. 10, 1936.

EDGAR LLOYD ROTHFUSS, Williamsport, Pa., to Miss Grace Clark of Carlisle, Sept. 8, 1936.

AL F. HOLLEY, Brewton, Ala., to Miss Vivian Thaxton at Porter in September 1936.

AUGUST M. HASEWINKLE, Markle, Ind., to Miss Rowena Dickman recently.

## Deaths

**Warren Stone Bickham**, formerly instructor in operative surgery at the Columbia University College of Physicians and Surgeons, New York, the New York Post-Graduate Medical School and Hospital and the New York Polyclinic Medical School and Hospital, aged 75, died Dec. 1, 1936, at his home in New York, of pneumonia and cardiovascular disease. Dr. Bickham was born in Shreveport, La., Aug. 23, 1861. He attended the University of the South, Yale University and the University of Louisiana and in 1887 received the M.D. degree from Tulane University of Louisiana Medical Department, New Orleans, and from the College of Physicians and Surgeons, Medical Department of Columbia College. For several years Dr. Bickham practiced in New Orleans, where he was visiting surgeon to the Charity Hospital, junior surgeon to the Touro Infirmary and demonstrator of operative surgery at Tulane. He later came to New York and, among other positions, was surgeon in charge of general surgery at the Manhattan State Hospital. He was the author of a well known textbook on "Operative Surgery," published in 1903, and seven volumes on "Operative Surgery," the last volume published in 1933. In 1906 he contributed sections on Amputations and Ligations in "Keen's System of Surgery." He had just completed a treatise on "Amputations and Artificial Limbs." Dr. Bickham was a fellow of the New York Academy of Medicine and of the American College of Surgeons. In 1925 he was awarded the honorary degree of doctor of laws by Tulane University.

**Charles Metcalfe Byrnes** • Baltimore; Johns Hopkins University School of Medicine, Baltimore, 1906; member of the American Neurological Association; past president of the Philadelphia Neurological Society; demonstrator in anatomy at his alma mater from 1902 to 1903; instructor in clinical neurology in 1909 and associate since 1918; adjunct professor of anatomy at the University of Virginia Department of Medicine, Charlottesville, 1906-1909; lecturer in neuropathology at the University of North Carolina in 1935; neurologist to the Church Home and Infirmary; visiting neurologist to the Baltimore Eye, Ear and Throat Hospital; consulting neurologist to the Peninsula General Hospital, Salisbury, Md.; contributed to Forchheimer's *Therapeutics of Internal Diseases* in 1913 and Tice's *Practice of Medicine* in 1920; aged 55; died, Nov. 29, 1936.

**James Allison Hodges** • Richmond, Va.; University of Virginia Department of Medicine, Charlottesville, 1883; member of the House of Delegates of the American Medical Association in 1923; emeritus professor of clinical, nervous and mental diseases at the Medical College of Virginia, and for many years president of the University College of Medicine; in North Carolina served as a member of the state board of health, associate editor of the *North Carolina Medical Journal*; fellow of the American College of Physicians; past president of the Richmond Academy of Medicine and member of the board of trustees; past president of the Medical Society of Virginia; in 1903 established the Hygeia Hospital and Sanatorium, which operated until 1920; aged 78; died, Dec. 15, 1936, at Greensboro, N. C.

**Thomas Long Catterson**, Spokane, Wash.; Detroit College of Medicine, 1887; member of the Washington State Medical Association; past president of the Spokane County Medical Society; fellow of the American College of Surgeons; at one time county physician and president of the city board of health; for many years on the staff of the Sacred Heart Hospital; aged 79; died, Oct. 20, 1936, of arteriosclerosis and senile dementia.

**William Louis Chapman** • Providence, R. I.; Boston University School of Medicine, 1897; member of the staff of St. Joseph's Hospital; on the editorial staff of the *Rhode Island Medical Journal*; was awarded the Alvarenga Prize of the College of Physicians of Philadelphia and the Fiske prizes of the Rhode Island Medical Society for various essays; music critic for local newspapers; aged 62; died, Nov. 15, 1936.

**William H. Bohart**, Vero Beach, Fla.; Rush Medical College, Chicago, 1891; formerly a practitioner in Chicago; at one time assistant clinical professor of surgery, Loyola University School of Medicine, Chicago; formerly on the staffs of St. Bernard's and Englewood hospitals, Chicago; for many years chief surgeon to the Chicago and Eastern Illinois Railroad Company; aged 67; died, Nov. 14, 1936.

**Alphonso Nicholas Codd**, Spokane, Wash.; Jefferson Medical College of Philadelphia, 1919; member of the Washington

State Medical Association, the American Academy of Ophthalmology and Oto-Laryngology and the Pacific Coast Oto-Ophthalmological Society; aged 42; on the staffs of St. Luke's Hospital and the Sacred Heart Hospital, where he died, Oct. 31, 1936, of pneumonia.

**William B. Wolf** • Baltimore; College of Physicians and Surgeons, Baltimore, 1896; member of the American Urological Association; fellow of the American College of Surgeons; formerly associate professor of genito-urinary diseases, University of Maryland School of Medicine; on the staff of the Maryland General Hospital; aged 67; died suddenly, Nov. 1, 1936.

**James Joseph Boucher**, Hartford, Conn.; College of Physicians and Surgeons, Baltimore, 1904; member of the Connecticut State Medical Society; fellow of the American College of Surgeons; on the staff of the Mount Sinai Hospital and St. Francis Hospital; aged 61; died, Nov. 14, 1936, of an accidental gunshot wound, while hunting in Colombia.

**William Porter Ellis** • Painesville, Ohio; Cleveland Medical College, 1896; Cleveland College of Physicians and Surgeons, Medical Department Ohio Wesleyan University, 1903; past president of the Lake County Medical Society; at one time member of the state legislature and coroner of Geauga County; aged 66; died, Nov. 8, 1936, of heart disease.

**Ray Arthur Edson**, Buffalo; University of Buffalo School of Medicine, 1907; member of the Medical Society of the State of New York, and the American Academy of Ophthalmology and Oto-Laryngology; assistant professor of ophthalmology at his alma mater; on the staff of the Buffalo General Hospital; aged 54; was found dead, Nov. 5, 1936.

**Jacob Clinton Atwell** • Butler, Pa.; Medico-Chirurgical College of Philadelphia, 1898; fellow of the American College of Physicians; past president of the Butler County Medical Society; served during the World War; on the staff of the Butler County Memorial Hospital; aged 62; died, Nov. 2, 1936, of pneumonia.

**Mary J. MacDuffee**, Devon, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1898; formerly on the staffs of the Children's and Polyclinic hospitals, Philadelphia; aged 86; died, Oct. 16, 1936, in the Presbyterian Hospital, Philadelphia, of arteriosclerosis and gangrene of the left leg.

**Ralph Raymond Harris** • Columbus, Ohio; Starling Medical College, Columbus, 1903; served during the World War; chief medical officer of the Veterans Administration in Cincinnati; on the staffs of the Grant and White Cross hospitals; aged 57; died, Nov. 12, 1936, of chronic myocarditis.

**Frank Webster Garber** • Muskegon, Mich.; Rush Medical College, Chicago, 1888; past president of the Muskegon County Medical Society; fellow of the American College of Surgeons; on the staffs of the Hackley Hospital and the Mercy Hospital; aged 77; died, Nov. 9, 1936, of coronary thrombosis.

**Joshua Shipley Devries** • Fremont, Neb.; Omaha Medical College, 1888; formerly county and city physician and coroner; past president and secretary of the Dodge County Medical Society; on the staff of the Lutheran Good Samaritan Hospital; aged 72; was found dead, Nov. 15, 1936.

**Edwin A. Long**, Johnson City, Tenn.; University of Louisville (Ky.) Medical Department, 1891; member of the Tennessee State Medical Association; at one time city health officer; on the staff of the Appalachian Hospital; aged 74; died suddenly, Oct. 27, 1936, at Palmer, Va., of myocarditis.

**William Albert Dearman** • Whitfield, Miss.; Tulane University of Louisiana Medical Department, New Orleans, 1906; fellow of the American College of Physicians; assistant superintendent of the Mississippi State Hospital; aged 58; died, Nov. 4, 1936, of a self-inflicted bullet wound.

**Thomas Vincent Buckley**, Girardville, Pa.; Medico-Chirurgical College of Philadelphia, 1910; member of the Medical Society of the State of Pennsylvania; deputy coroner; aged 52; died, Nov. 6, 1936, in the Sacred Heart Hospital, Allentown, of cerebral hemorrhage.

**Charles Eduard Max Fischer**, Chicago; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1907; formerly associate professor of medical biology, histology and embryology at his alma mater; aged 55; died, Nov. 16, 1936.

**H. Manning Brabham**, Ehrhardt, S. C.; Vanderbilt University School of Medicine, Nashville, Tenn., 1893; member of the South Carolina Medical Association; aged 70; died, Nov. 19, 1936, in the Tri-County Hospital, Orangeburg, of injuries received in a fall.

**Alton Bartlett Simonson**, Elsie, Mich.; Detroit College of Medicine and Surgery, 1926; member of the Michigan State Medical Society; on the staff of the Clinton Memorial Hospital, St. Johns; aged 35; was instantly killed, Oct. 22, 1936, in an automobile accident.

**Joseph P. Smyth** @ Chicago; Rush Medical College, Chicago, 1888; clinical professor of medicine, Loyola University School of Medicine; on the staffs of St. Bernard's Hospital and the West Side Hospital; aged 74; died, Dec. 15, 1936, of coronary thrombosis.

**Fairfax Irwin** @ Senior Surgeon, U. S. Public Health Service, Washington, D. C.; University of Pennsylvania Department of Medicine, Philadelphia, 1877; served during the World War as adviser on sanitation for the U. S. Navy; aged 82; died, Oct. 28, 1936.

**William Frederick McBride** @ Dayton, Ind.; Rush Medical College, Chicago, 1895; past president of the Tippecanoe County Medical Society; aged 65; died, Oct. 4, 1936, in a hospital at Lafayette, of a benign tumor of the prostate and myocarditis.

**Mott Hunton Arnold**, San Diego, Calif.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1907; member of the California Medical Association; aged 53; died, Dec. 9, 1936, of coronary sclerosis.

**Francis Marion Davis** @ Greenville, N. C.; Harvard University Medical School, Boston, 1931; on the staff of the Pitt Community Hospital; aged 32; was instantly killed, Nov. 15, 1936, in an automobile accident near Morehead City.

**James Edmund Downs**, San Diego, Calif.; College of Physicians and Surgeons, Keokuk, Iowa, 1878; Rush Medical College, Chicago, 1889; aged 82; died, Oct. 16, 1936, of hypostatic pneumonia and chronic myocarditis.

**Walter Louis Finn**, Iuka, Ill.; Missouri Medical College, St. Louis, 1899; member of the Illinois State Medical Society; state senator; served during the World War; aged 61; died suddenly, Nov. 7, 1936, of angina pectoris.

**Allen Collins Butterfield** @ Grand Rapids, Mich.; Grand Rapids Medical College, 1906; aged 59; on the staff of St. Mary's Hospital, where he died, Nov. 13, 1936, of embolism, following an operation for appendicitis.

**Edward Alfred Brace**, Ellington, Conn.; University of Vermont College of Medicine, Burlington, 1911; served during the World War; aged 57; died, Oct. 22, 1936, in the Veterans Administration Facility, New York.

**John D. Dunham**, Pattonsburg, Mo.; College of Physicians and Surgeons, Keokuk, Iowa, 1877; member of the Missouri State Medical Association; formerly member of the state legislature; aged 81; died, Oct. 6, 1936.

**Starr Ford**, Cincinnati; Medical College of Ohio, Cincinnati, 1897; formerly instructor in medicine at the University of Cincinnati College of Medicine; served during the World War; aged 71; died, Nov. 16, 1936.

**Theodore Tillman Shackelford**, Haskell, Okla.; University of Louisville (Ky.) Medical Department, 1910; past president of the board of education; served during the World War; aged 50; died, Oct. 18, 1936.

**Charles Roy Vickery**, South Bend, Ind.; Hahnemann Medical College and Hospital, Chicago, 1901; member of the Indiana State Medical Association; aged 65; died, Oct. 10, 1936, of coronary thrombosis.

**William S. Stewart**, Finleyville, Pa.; Medico-Chirurgical College of Philadelphia, 1887; served during the World War; past president of the board of education of Braddock; aged 72; died, Oct. 19, 1936.

**John A. Tuthill**, Le Roy, Ill.; State University of Iowa College of Medicine, Iowa City, 1881; formerly mayor and member of the school board; aged 81; died, Oct. 7, 1936, of angina pectoris.

**Edward Richardson Gardner** @ Montrose, Pa.; Jefferson Medical College of Philadelphia, 1882; secretary of the Susquehanna County Medical Society; aged 83; died suddenly Nov. 3, 1936.

**Norman Halkier Goodenow**, Los Angeles; Rush Medical College, Chicago, 1892; member of the California Medical Association; aged 66; died, Oct. 14, 1936, of subacute bacterial endocarditis.

**Mearle C. Fox**, Westlake, Ore.; Willamette University Medical Department, Salem, 1909; member of the Pacific Coast Oto-Ophthalmological Society; aged 54; died, Oct. 31, 1936, in Los Angeles, of heart disease.

**Willis Wade Rutland**, Lagrange, Ga.; Southern Medical College, Atlanta, 1889; aged 73; died, Oct. 24, 1936, in the Dunson Hospital, of pyelonephritis and hypertrophic prostatitis.

**John Irvin Gossett**, Rule, Texas (registered by Texas State Board of Medical Examiners, Act of 1907); aged 61; was found dead in bed, Oct. 24, 1936, of coronary thrombosis.

**George W. Torrey**, Chicago; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1895; also a dentist; aged 65; died, Dec. 12, 1936, of coronary thrombosis.

**John Logan Avey**, Los Angeles; University of Louisville (Ky.) Medical Department, 1891; served during the World War; formerly state senator; aged 71; died, Oct. 17, 1936.

**Joseph Henry Witt**, Waco, Texas; Tulane University of Louisiana Medical Department, New Orleans, 1885; aged 80; died, Oct. 27, 1936, in a local hospital, of senility.

**Henry Adolph Siebenborn**, Brooklyn; Cornell University Medical College, New York, 1899; aged 76; died, Oct. 26, 1936, of carcinoma of the right lung and arteriosclerosis.

**Henry S. Hadsel**, Oxford, Ohio; College of Physicians and Surgeons, Keokuk, Iowa, 1882; member of the Iowa State Medical Society; aged 84; died, Oct. 6, 1936.

**Neils Alfred Peterson**, Soldiers Grove, Wis.; Milwaukee Medical College, 1901; member of the State Medical Society of Wisconsin; aged 59; died, Oct. 30, 1936.

**Albertus G. Greenawalt**, Runnells, Iowa; Kentucky School of Medicine, Louisville, 1893; aged 68; died, Oct. 13, 1936, in Des Moines, of carcinoma of the pancreas.

**Elisha L. Lee**, Bridgeport, Ala.; University of Nashville (Tenn.) Medical Department, 1872; for many years bank president; aged 96; died, Oct. 16, 1936.

**Thomas E. V. Fariss**, Fairfield, Iowa (licensed by Iowa State Board of Medical Examiners in 1886); aged 90; died, Oct. 15, 1936, of myocarditis.

**Harold Talbot Cartwright**, East Rockaway, N. Y.; Long Island College Hospital, Brooklyn, 1917; aged 47; died, Oct. 25, 1936, of coronary occlusion.

**John Eddowes Beebe**, Chicago; Gross Medical College, Denver, 1895; aged 84; died, Nov. 14, 1936, of coronary thrombosis and arteriosclerosis.

**John Francis Keenan**, Brentwood, Md.; Howard University College of Medicine, Washington, D. C., 1885; aged 79; died suddenly, Oct. 12, 1936.

**Robert Wilfred Moss Clark**, Niagara Falls, Ont., Canada; Queen's University Faculty of Medicine, Kingston, 1934; aged 32; died, Oct. 25, 1936.

**James Percival Leahy**, New Bedford, Mass. (licensed in Massachusetts in 1902); aged 61; died, Oct. 31, 1936, of coronary thrombosis.

**Samuel Breese Smith**, Chicago; Dartmouth Medical School, Hanover, N. H., 1893; aged 73; died, Oct. 8, 1936, of cerebral hemorrhage.

**Lewis Gaddy**, Los Angeles; University of Tennessee Medical Department, Nashville, 1905; aged 66; died, Oct. 22, 1936, of arteriosclerosis.

**John Scoular Goodfellow**, Morrisburg, Ont., Canada; Trinity Medical College, Toronto, 1894; aged 65; died in October 1936.

**Melbourne F. Keith**, Moncton, N. B., Canada; University of the City of New York Medical Department, 1882; died in October 1936.

**Willis A. Mansfield**, Washington, Ill.; Chicago Medical College, 1884; aged 78; died suddenly, Oct. 30, 1936, of heart disease.

**Frank Lewis Anderson**, McIntire, Iowa; Louisville (Ky.) Medical College, 1893; aged 67; died, Oct. 20, 1936, of erysipelas.

**Henry L. Bartlett**, Templeton, Calif.; Northwestern University Medical School, Chicago, 1901; aged 66; died, Oct. 5, 1936.

**Alonzo L. Share**, Oklahoma City; Detroit College of Medicine, 1892; aged 72; died, Oct. 6, 1936, of cerebral hemorrhage.

**E. W. Robberson**, Gainesville, Texas (licensed in Texas under the Act of 1907); aged 85; died in October 1936.

**Jacob Jacobson**, St. Louis; Missouri Medical College, St. Louis, 1892; aged 67; died, Oct. 31, 1936, of heart disease.

**Milton B. Deck**, Bennet, Neb.; University of Maryland School of Medicine, Baltimore, 1879; died, Oct. 4, 1936.

### ACCELERATED SERUM SICKNESS

*To the Editor:*—In their article on "The Therapy of (Horse) Serum Reactions" in *THE JOURNAL*, Nov. 21, 1936, Fantus and Feinberg state that the symptoms of "accelerated serum sickness" are "similar to those described under serum sickness" and that "the manifestations may differ in no way from those previously described in serum sickness, but usually they are much more severe and alarming."

Some authorities on this subject still confuse two entirely different phenomena; namely, allergic shock and serum sickness. The only symptom in common is urticaria and even this symptom is occasionally lacking. (Waldbott, G. L.: *The Prevention of Anaphylactic Shock with a Study of Nine Fatal Cases*, *THE JOURNAL*, Feb. 6, 1932, p. 446.) Allergic shock is always the result of a previously existing sensitization, regardless of whether or not it is inherited or acquired, and is characterized only by allergic symptoms. This reaction is due to an overdose of antigen above the individual's tolerance and—as it does in the anaphylactic animal experiment—it establishes a greater protection against the antigen in the patient. It is true that occasionally death has occurred so rapidly, particularly following intravenous or accidentally intravenous injections, that no symptoms could be observed. While such a situation accounts for greater difficulties in diagnosis, my experience with reactions following injections of pollen extract has given me sufficient clinical data to identify such an asymptomatic reaction definitely with allergic shock. The other type of reaction ("serum sickness" or "serum disease") is the expression of certain immunologic changes in the system of the non-allergic or allergic person which, as the authors admit, renders the individual either sensitive or more sensitive to this antigen. Its clinical course parallels closely that of an acute infection with hyperpyrexia and joint and glandular swelling and is at great variance with any manifestations observed in allergic diseases. The two types of reaction behave in the same characteristic manner regardless of what antigen is injected. (Waldbott: "Allergic" Shock from Substances Other Than Pollens and Serums, *Ann. Int. Med.* 7:1308 [April] 1934.)

Various other statements in this article are open to criticism: In view of the fundamental experiments of Bret Ratner, many find it difficult to adhere to the old theory that allergic shock can occur only in naturally sensitive individuals and that the same symptom complex should be called "anaphylactic" shock if the patient's sensitivity is assumed to be acquired. This more or less theoretical question becomes of profound practical importance when the authors advocate, as they do, a different treatment for both types of shock and state that to the "naturally sensitive" patient no horse serum should be given "under any circumstances or in any way." Even if a distinction between acquired and natural sensitivity on the basis of different types of antibodies and heredity were possible, there is not the slightest evidence either experimentally or clinically that human sensitivity responds differently to treatment according to its origin. I believe this is true regardless of whether or not man can be "completely" desensitized in contrast with the anaphylactic animal, an observation which is partially responsible for the distinction of "anaphylactic" and "allergic" shock.

The authors do not state that "accelerated serum sickness" is actually an intensified form of allergic shock which is due either to an accidental puncture of, and injection into, a small vein or to extreme sensitivity to serum which is administered subcutaneously. Accordingly, they do not discuss one of the most useful measures for preventing these dangerous reactions, namely, the guarding against an accidental puncture of venules, by selecting the proper site of injection, by repeated with-

drawals of the plunger before and during the injection for evidence of blood, by watching for bleeding after the injection, and by other precautions recently outlined elsewhere by M. S. Ascher and myself (*The Role of Accidental Puncture of Veins in the Production of Allergic Shock*, *Ann. Int. Med.* 9:1232 [March] 1936).

The value of rapid hyposensitization cannot be summarily dismissed, as it is done by the authors, merely because its original technic as advocated by Besredka and Freeman is not devoid of danger. There is increasing evidence that this method can be carried out as a safe procedure. Since our preliminary report on this subject (*Rapid Hyposensitization*, *J. Allergy* 6:93 [Nov.] 1934), Ascher and I have studied more than 300 patients treated with this method. We found that rapid hyposensitization is not only safe but in many instances the method of choice when quick action is needed. The key for its success lies in observing the following points: the starting with a sufficiently low dose, the careful gaging of subsequent doses, and the adjustment of the time interval between injections as determined by the degree of the local swelling from each individual injection.

GEORGE L. WALDBOTT, M.D., Detroit.

### THE INDIFFERENCE OF OUR MEDICAL SCHOOLS TO CAREERS IN PUBLIC HEALTH

*To the Editor:*—A recent inquiry into progress of New Mexico medical students in the field of public health reveals an astonishing lack of interest on the part of the deans of our medical schools in public health as a career for their future graduates.

In the last Educational Number of *THE JOURNAL* (Aug. 29, 1936, p. 664) was given a list of the medical schools showing the students registered by the state of their birth. It happens that in New Mexico only physicians who have lived for two years in this state are eligible for positions in the field of public health. In order that a record of eligible physicians in the younger age groups might be available in our office, I wrote to the dean of each school where New Mexico students are registered the following letter:

On page 664 of the Educational Number of *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* I find that .... New Mexico students are registered in your school. I am very anxious to keep a record of the medical students from this state who may possibly become interested in public health service in order that the most promising of them may have an opportunity of postgraduate study in public health at the expense of the state if they are unable to afford such postgraduate study themselves. To this end I have prepared a card index and am enclosing herewith the cards relative to the students in your school and would be very grateful if you would be so good as to have them completed and returned to this office.

Of the nineteen so addressed, five did not answer at all. Of the remaining fourteen, only three replied to the inquiry regarding the student's interest in a career in public health, unless it was to say that of course they could not reply to this inquiry. Most deans apparently made the assumption that we should ask the student himself about his interest. While there was a general spirit of willingness to cooperate in this investigation on the part of the deans, only three medical schools showed a sense of responsibility in seeking to secure for their graduates an opportunity to pursue a career in public health. They were the University of Chicago, the University of Colorado and the College of Medical Evangelists in Los Angeles.

It is not clear whether this indifference to the student's future career is limited to the field of public health or whether perhaps deans of medical schools differ from the deans of other schools in feeling that a student's future career is entirely his own business and that the university has no responsibility in regard thereto.

J. ROSSLYN EARP, DR.P.H., Santa Fe, N. M.  
Director, New Mexico Bureau of Public Health.

## Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

### GLYCOSURIA IN PNEUMONIA AND OTHER INFECTIONS

To the Editor:—July 14, 1936, I sent to the hospital a youth of 20, very sick with left lower lobar pneumonia, marked cyanosis, a temperature of 103 F., pulse 130, respiration 48, pink sputum, vomiting frequently for the past two days, and taking almost no nourishment. At the hospital, oxygen was at once administered. The white blood count was 23,500 and blood sugar 0.166 Gm. per hundred cubic centimeters. The pneumonia proved to be type II. Immediately I had 10 units of insulin given by hypodermic injection, repeated three times daily for the next two days and then reduced to 4 units for two days, with none thereafter. The blood sugar on admission at noon after two days of vomiting was 0.166 Gm.; next morning (the 15th) it was 0.136 Gm., on the 16th it was 0.090 Gm. before breakfast and on the 20th after breakfast it was 0.111 Gm., the day of discharge from the hospital. The patient had no history of diabetes. Urine specimens were negative for sugar. He never cared for sweets. In *THE JOURNAL*, Jan. 18, 1936, page 259, is a brief abstract from Moscow telling of Drs. Sinelnikov, Perchik and Doroklova testing twenty-three cases of pneumonia, all showing high blood sugar and recovery occurring in all but one on the administration of insulin. I have not been able to locate other studies of blood sugar in pneumonia or severe acute colds. As a result of my observation I should invite further studies. A number of problems present themselves: 1. Is high blood sugar frequently present in pneumonia cases? If so, would not this provide a good growth medium for the offending bacteria? 2. If the blood sugar is usually high in pneumonia cases should not insulin be a natural additional weapon in combating pneumonia? 3. If high, when did blood sugar rise in any case of pneumonia? Was it during the prepneumonic upper respiratory infection? If so, could early giving of insulin possibly be a new means of preventing some pneumonias? 4. In the cases of high blood sugar, what is the cause of the sudden hypo-insulinemia (if it is such), toxemia, anoxemia or otherwise? Numerous other questions could be suggested. Owing to the remarkably speedy recovery in the case reported following the mentioned observation, I felt that widespread good could come to other physicians handling similar cases and possibly stimulate the study of blood sugars in pneumonias in various centers of the country. HENRY RAILE, M.D., Salt Lake City.

ANSWER.—Transient glycosuria has often been noted in infectious diseases. It has been found in diphtheria, scarlet fever, typhoid, influenza, infections with suppuration, Asiatic cholera, malaria, carbuncle or gangrene, and pneumonia.

A lowered dextrose tolerance was reported by Hamman and Hirschman in lobar pneumonia and acute tonsillitis (*Arch. Int. Med.* 20:761 [Nov.] 1917). Abnormal blood sugar curves in many acute infections were found by Olmsted and Gay, by Labbé and Boulon and by Andresen and Schmidt. Patients with oral sepsis or general sepsis frequently have a lowered carbohydrate tolerance. A deficient metabolism of carbohydrates has been described by Pemberton in arthritis.

Animal experiments by Rosenthal, by Tisdall, Drake and Brown, by Sweeney and Lackey and by Williams and Dick also indicate a decreased tolerance for dextrose in experimental infections.

It is now well known that infections in patients with diabetes mellitus cause a marked reduction of dextrose tolerance, and large doses of insulin are necessary to control an acidosis in such patients. An acute infection may be the precipitating cause of coma in a diabetic patient. Diabetes not infrequently develops after some acute infectious disease (typhoid, scarlet fever, influenza, diphtheria, tonsillitis, syphilis, rheumatic fever, mumps, focal infection, pneumonia). Diabetes may accompany or follow an acute pancreatitis, and some writers claim a relationship to gallbladder disease.

The toxemia of infectious diseases most likely reduces the production of insulin, as insulin injections restore the carbohydrate tolerance. The toxic products of many bacteria have a harmful effect on the islets of Langerhans and may either cause diabetes mellitus to develop or aggravate the disease if it is already present. In any infectious disease in which a definite disturbance of carbohydrate metabolism develops, insulin will be of value in sparing the islets and thus aid in the recovery or regeneration of these structures.

Williams and Dick (*Arch. Int. Med.* 50:801 [Dec.] 1932) studied the dextrose tolerance in 108 patients with acute infectious diseases. There were eight cases of pneumonia. The amount of dextrose in the twenty-four hour urine averaged 1.66 Gm. Three of these patients were reexamined after the crisis, with an average of 0.83 Gm. In two patients the reduced

tolerance persisted long after recovery from the pneumonia and it was necessary to restrict carbohydrates for several weeks. In two of five influenza patients there was a decided loss of tolerance. These two authors found that in patients with acute infections the most marked decrease in tolerance usually occurred in those who were severely ill or who had complications, or in those in whom two or more contagious diseases occurred in quick succession. The fasting blood sugar was found to be high in some cases of pneumonia. Warren and Root (*Am. J. Path.* 1:415 [July] 1925) have described necrosis of the islet cells in pneumonia.

From the data it is evident that a temporary glycosuria occurs in many acute infectious and contagious diseases. This is accompanied by an increased fasting blood sugar and reduced carbohydrate tolerance. There is most likely some damage to the islets of Langerhans with a reduced insulin production. The decreased tolerance may last for weeks or months. Insulin injections improve the tolerance for dextrose.

A high blood sugar is often found in pneumonia, and in such patients the use of insulin would be of definite value. The tendency to feed large amounts of carbohydrate may be a factor in exhausting the islet cells.

Insulin is an additional weapon in combating pneumonia in diabetic patients only so far as it improves the metabolism and general condition of the patient and thus increases resistance to the pneumococcus. It has been demonstrated that types I and II pneumococci are rarely found in healthy throats but are often found in the throats of persons in contact with type I and II pneumonia patients. Individuals who are exposed to pneumococci and who do not possess sufficient immunity will contract the disease.

The blood sugar rise in pneumonia is due to the toxemia and therefore develops after invasion of the lung and perhaps the blood stream by pneumococci. It cannot at present be stated that a prepneumonic infection of the upper respiratory tract leads to pneumonia because it sometimes causes a rise in the blood sugar. The prevention of pneumonia is based on a satisfactory immunization against the toxic agent of the pneumococcus and isolation of the patients with this disease.

In the cases presenting a high blood sugar the cause of the hypo-insulinemia is most likely damage to the islets of Langerhans produced by the toxic polysaccharides found in the capsule of the pneumococcus.

### ASTHMA

To the Editor:—Please describe the procedure in testing the sensitivity of patients suffering from asthma from causes in the home. Is any new symptomatic treatment being given now? I will appreciate any information with regard to the newer views and treatment of patients with asthma. Please omit name if published. M.D., Georgia.

ANSWER.—Several procedures may be followed. The safest method is to do scratch tests first. This consists of scarifying the skin, going through only the most superficial layers and being very careful not to draw blood. Twentieth normal sodium hydroxide is applied to the scratch and a small quantity of the dried allergen is rubbed into the sodium hydroxide. These materials may be purchased through several of the drug houses. The most common inhalant offenders are cottonseed, kapok, wool, silk, house dust, feathers, orris root, pyrethrum, mohair, cow hair, dog hair, cat hair, horse dander, rabbit hair and flax seed. If these are negative, intracutaneous tests with sterile liquid extracts may be tried, the prescribed concentrations being used. A further procedure that may be used is to take samples of various materials in the home, soak them in twentieth normal sodium hydroxide for a few hours, and use the supernatant fluid for scratch tests.

If any materials give reactions, they should be completely removed from the environment. If this is impossible, such objects as mattresses and pillows may be covered with rubberized cloth, with double stitching and tape used over the seams.

Of course, complete pollen and food tests should also be done. Molds have been shown to be factors in the etiology of some cases of asthma and should also be used in testing such a case.

The foods that react positively are eliminated from the diet. The pollens and molds that react are used for treatment.

For symptomatic treatment epinephrine hypodermically and ephedrine orally are still most important. Epinephrine may also be given by inhalation in 1:100 solution in a special nebulizer (De Vilbiss No. 44). Sedatives, as bromides, the barbiturates or chloral hydrate, are frequently of marked benefit. In intractable asthma, whisky, especially at night, tends to relieve the spasm.

Vaccines (autogenous or stock) may be used intracutaneously in gradually increasing doses.

Nonspecific protein therapy by means of injection of peptone, typhoid vaccine or milk protein may be used.

If inhalants such as house dust are used in treatment, they are best given intracutaneously.

Recently several reports on desensitization with histamine have appeared in the literature (Dszinich, A.: *Klin. Wchnschr.* 14:1593, 1935). Iodized oil instilled into the trachea has yielded good results in cases in which bronchiectasis is associated (Anderson, W.: *J. Allergy* 4:44 [Nov.] 1932). Inhalation of helium gas has been reported (Barach, A. L.: *Ann. Int. Med.* 9:739, 1935); also carbon dioxide inhalation (Farago, P.: *Ztschr. f. d. ges. exper. Med.* 91:114, 1933), acid therapy (Beckman, H.: *J. Allergy* 1:496 [Sept.] 1930), desiccated suprarenal gland (Barbour, D.: *Arch. Pediat.*, March 1, 1936), dextrose intravenously (Matzger, E.: *J. Allergy* 3:599, 1932) and ether anesthesia in intractable asthma (Troisier, J., and Boquien, Y.: *Bull. et mém. Soc. méd. d. hôp. de Paris* 47:310 [March 2] 1931).

#### LYMPHEDEMA OF LEGS

*To the Editor:*—A woman, aged 45, has had swelling of the right leg from the knee downward, for the past two years. In the morning the swelling is down, but toward evening the right leg is twice the size of the left leg. The swelling does not pit on pressure and the leg does not produce pain. The surface temperature seems the same as on the left leg. The only complaint the patient has is that she resents the massiveness and appearance of the limb when reminded by her friends of the difference in size. She refuses to wear an elastic stocking. When she came to me on her first visit I ruled out hernia and appendicitis. No operations had been performed. There was no liver enlargement, abdominal disturbance, dysuria, nocturia or urinary frequency. The specific gravity of the urine was 1.030. There was no albumin or sugar. Blood pressure was 150 systolic, 80 diastolic. Treatment consisted of Diuretic no. 1, Niemeyer's blue mass squill and digitalis, 1 grain (0.065 Gm.), one tablet every four hours for four days, Apiol and Digitalis tablets made by Upjohn, potassium citrate, 5 grains (0.3 Gm.), one of each after meals with one-half glass hot water. One week later the blood pressure was 140/82, the leg was less swollen, and the medication seemed to improve the condition. One month later she returned for treatment again. In the meantime she had the foot roentgenographed and it showed no bony pathologic changes or misplacements. A foot specialist taped the foot and prescribed an anklet to be worn. Every time I repeat the medication the leg becomes less swollen; as soon as medication ceases, the swelling returns. If the kidney is responsible for this impaired circulation, why doesn't the edema appear bilateral? Could a stricture of the saphenous opening be a cause for this condition? The patient has had one child; could there be an association of childbirth with this condition? The impairment of circulation seems to be localized, and the peculiar thing is that there is no pitting on pressure. Could this be one of those rare cases in which there is an impairment in the circulation of the lymphatics; but wouldn't this cause pitting? If there is a cirrhosis of the liver present, shouldn't there be a bilateral phenomenon rather than a localized condition? I am at a loss to inform the patient as to the cause of the swelling and I don't want to resort to the continued use of pills to allay the condition but would rather have you advise me as to how I should handle the case and advise the patient accordingly. I did not examine this woman internally to ascertain the presence of a fibroid, which might be responsible to vessel pressure internally and may cause impeded circulation.

P. R. EVANS, M.D., Tower City, Pa.

*ANSWER:*—The fact that only one leg is involved and that there is no evidence of constitutional disease, particularly of the heart or kidneys, strongly suggests that the swelling is due to local disease. Such a condition could arise as a result of chronic venous insufficiency caused by old thrombophlebitis or obstruction of the iliac vein from pressure, such as that exerted by a pelvic tumor. In thrombophlebitis the onset of swelling in the leg is usually fairly abrupt. In venous insufficiency that is caused by external venous pressure, it is more gradual. In either event the superficial veins of the lower part of the affected leg should be abnormally prominent and should empty more slowly than those of the other leg on elevation of the legs above the level of the heart. A more likely possibility is that this is a case of chronic lymphedema. In lymphedema it may be difficult to demonstrate actual pitting of the skin. The skin becomes coarse and thick, and the superficial fascia becomes markedly thickened and fibrotic. A roentgenogram taken for detail of the soft tissue will reveal the presence of a marked mottling in the subcutaneous region, caused by lymph pockets. Lymphedema may be attributable to recurrent episodes of lymphangitis of the skin which simulate local erysipelas. It may be caused by sclerosis of the iliac and inguinal lymph nodes resulting from lymphangitis, or it may be caused by invasion of the pelvic lymph vessels and lymph nodes by malignant tumors. Some cases of lymphedema are associated with trichophytosis of the feet, but in this type, as well as in the type that is caused by filariasis, there are usually recurrent episodes of lymphangitis and lymphadenitis. In another group are the congenital and hereditary types of lymphedema. A still further group, designated as lymphedema praecox, appears without any

recognizable etiologic factor. (Allen, E. V., and Ghormley, R. K.: Lymphedema of the Extremities: Etiology, Classification and Treatment; Report of 300 cases, *Ann. Int. Med.* 9:516 [Nov.] 1935.) In lymphedema it is usually possible to demonstrate some reduction in the size of the leg after the patient has been placed in bed, with the leg elevated to an angle of 30 degrees for forty-eight hours, but on account of the proliferating fibrosis in the superficial fascia the leg does not return to normal size, even after prolonged elevation. The only satisfactory treatment for lymphedema consists in the use of heavy elastic stockings or bandages, and operation of the Kondoleon type.

#### EFFECTS OF EXERCISE TEST ON EXTRASYSTOLES, MURMURS AND DIASTOLIC PRESSURE

*To the Editor:*—Kindly give your interpretation of the following in Queries and Minor Notes: Extrasystoles that do not disappear or even appear after the heart tolerance test, consisting of fifteen bends or twenty-five hops. Systolic murmurs that disappear in youth after the exercise test; also systolic murmurs, "no other heart findings," which disappear after exercise at the age of 40 or over, also drop in the systolic pressure after exercise test. It was stated that it is normal for the diastolic pressure to be elevated after the exercise test. My experience has been that it often drops even in young adults.

H. M. STRACHAN, M.D., Cleveland.

*ANSWER:*—Premature ventricular contractions will usually disappear during the exercise but reappear in the rest following the exercise. Occasionally, when not present before the exercise, they may appear in the rest after the exercise. Premature auricular contractions may follow a similar course or may appear after exercise and be more frequent after exercise and not disappear, or they may even first appear during exercise.

Systolic murmurs come and go with changes in tonus of the heart muscle or relative changes in different portions of the heart muscle. They may disappear after exertion as tonus increases or appear with conditions that decrease tonus, or because of the increased minute volume of blood passing through the valves.

Diastolic pressure usually follows the systolic and is usually more elevated following exercise. A fall in diastolic pressure after exercise has been assumed by some to be an index of myocardial damage. This may be true in some cases, but other normal physiologic factors may also be factors, and it is not safe to base an opinion on this alone.

#### AUSCULTATORY DETERMINATION OF BLOOD PRESSURE

*To the Editor:*—Will you please explain to me the following: In life insurance examinations with reference to blood pressure, I notice that they say diastolic fourth point and diastolic fifth point. Just what is meant by that?

JOSEPH HALTON, M.D., Sarasota, Fla.

*ANSWER:*—In the auscultatory determination of the arterial tension, five distinct phases of sound are heard. Each phase may vary considerably in duration and character, but the sequence is invariable. With inflation of the cuff to pressure above the systolic level, no sound is heard at the cubital fossa; but as the cuff is deflated one hears first sharp staccato clicks, which resemble normal cardiac sounds. This is the first phase, and the pressure at which these clicks appear is taken as the systolic pressure. The second phase is longer than the first and the sounds are best described as hissing or blowing murmurs. These arise because of whorls and eddies in the blood below the point of constriction. These sounds are transitory and disappear if constriction is maintained at this level of pressure. Occasionally, despite relatively rapid deflation, the sounds of the second phase disappear to cause the "auscultatory gap"; this phenomenon presumably occurs only in instances of hypertension and/or aortic stenosis. The transition to the third phase of sound is normally not sharply defined; the murmurs change to dull thuds, distinctly louder. The character of the thuds heard in the third phase varies with the condition of the arterial wall. When hypertonus of the artery exists and the walls are tense and rigid, the tones are louder than when the wall is relatively flaccid. The fourth phase appears when the thuds are abruptly muffled. The fourth phase is usually quite short and is soon followed by silence, which is the fifth point of change. Occasionally the fourth phase is prolonged and there is a considerable span between the appearance of muffling (fourth point) and silence (fifth point).

For many years the insurance companies were in the habit of requesting their examiners to determine the diastolic tension at the fifth point (in other words, at the disappearance of sound). However, it has been demonstrated repeatedly that this is incorrect. The true diastolic tension should be read at

the onset of the fourth phase, where the booming thuds are suddenly muffled. The average difference between these two points is about 5 mm. of mercury, but the error may be as much as 55 mm. As rating tables were based on the original fifth point diastolic tension, underwriters felt that the error was compensated for. It is wrong, nevertheless, to correct one error by introducing another. The present tendency of insurance medical directors to request both readings at the fourth and fifth points is to obtain figures for revision of their statistical data. The length of the fourth phase is variable and thus the error introduced by fifth point readings is inconstant. Just how inconstant this is can best be demonstrated by thousands of observations.

#### "C. N." DISINFECTANT AS INDUSTRIAL HAZARD

*To the Editor:*—I have recently had a case of gangrene of the fingers. This apparently occurred after exposure to a solution of C. N. in hot water. Would you kindly let me know the chemical composition of this product and whether there have been any case reports in the literature of gangrene following its use. Kindly omit name and address.

M.D., New York.

**ANSWER.**—C. N. is a coal tar disinfectant believed to be manufactured by the West Disinfecting Company and said to represent creosote containing aromatic hydrocarbons of double nucleus, the pyridine and chinoline bases, and the three isomeric cresols—ortho-, meta- and para-. Of the three cresols the ortho- and the para- are more toxic than phenol. Tricresol is a mixture of the isomeric cresols and is about nine-tenths as toxic as phenol. Saponated solution of cresol is a somewhat similar mixture of coal tar cresols along with soap solution. From the work of C. D. Harrington (*THE JOURNAL*, Feb. 13, 1909, p. 575) it may be recognized that the local effects of cresol are similar to those produced by phenol. Since phenol is well recognized as a source of gangrene, it is a tenable belief that cresols likewise may produce gangrene under conditions of appropriate exposure. Naturally, the probability of damage from cresols increases with the strength of the solution to which exposure is provided. Extensive discussion of the toxic properties of cresols (but without reference to C. N.) may be found in "Legal Medicine and Toxicology," by Peterson, Haines and Webster (ed. 2, Philadelphia, W. B. Saunders Company, 1926, second volume) and "Occupation and Health" (Geneva, International Labor Office, 1930, first volume).

#### EXOPHTHALMIC GOITER

*To the Editor:*—A girl of 16 is suffering from hyperthyroidism of probably a year's duration. The basal metabolism before treatment was plus 39 and after three weeks' bed rest, iodine therapy and ample diet was plus 17, with increase of weight from 109 to 121 pounds (49 to 55 Kg.) and improvement in well being, although nervousness, fatigue and emotional instability persist. The pulse at rest is 90. The heart shows no evidence of hypertrophy or impairment, although after an effort test the pulse failed to return to the previous rate in three minutes. The blood pressure remains 120 systolic, 72 diastolic. There is no evidence of other illness, except for a negative Wassermann reaction with plain antigen, 4 plus with cholesterinized antigen and 1 plus with the Kahn test. However, nothing in the history or examination tends to corroborate this observation. A thyroid specialist advises against roentgen therapy, as he says that results are too dubious and subsequent operation would be made very difficult as a result of fibrosis. Any advice you may give me as to my further handling of this case will be appreciated, especially as to the preference of irradiation or surgery. Kindly omit name.

M.D., New Jersey.

**ANSWER.**—The administration of iodine apparently does not eliminate the underlying factor responsible for exophthalmic goiter or primary hyperthyroidism, if one prefers so to designate this disease. Iodine, however, does control to a varying degree the symptoms of exophthalmic goiter. In a small proportion of cases it temporarily lowers the basal metabolic rate to within normal limits and for the time being completely eliminates the symptoms; later, in spite of the continued use of iodine, the basal metabolic rate returns to abnormally high levels and the symptoms recur. In a still smaller proportion of the cases, the basal metabolic rate remains within normal limits and the symptoms are completely controlled as long as the use of iodine is continued.

In those cases in which iodine either temporarily or permanently eliminates the symptoms, such complete control usually, but not always, results within two weeks following the institution of treatment. In the case described, however, iodine has not completely controlled the symptoms and the basal metabolic rate still is plus 17 per cent even though iodine has been administered for a period of three weeks. Furthermore, the rapid gain in weight that occurred in this case is not necessarily an indication that the disease is being controlled. In many cases

of exophthalmic goiter, particularly in girls, a rapid gain in weight may occur during a period when the basal metabolic rate is very high and when the disease is progressing; the weight may reach a level that is well above the individual's normal weight.

If in this case the diagnosis is correct and the criteria are all as they appear to be, a partial thyroidectomy would seem to be the treatment of choice. This conclusion would be materially strengthened if palpation revealed that each lobe of the thyroid gland was sufficiently large to be readily grasped between the thumb and fingers of the examining hand and if the lobes were found to be relatively firm to palpation. The positive serologic tests in this case may be false positives. The case should be reconsidered from this angle, however, after the symptoms of exophthalmic goiter have subsided, in the course of from two to four months, and possibly an examination of the spinal fluid should be made.

#### MULTIPLE SCLEROSIS

*To the Editor:*—A white man, aged 32 years, fell down some steps eight years ago. He noted no ill effects at the time but two months later his right foot seemed to slap when walking. This sensation gradually changed to one in which the leg felt dead and dragged when he walked. There was no loss of sensation, pain, heat or position. He had no pain but had frequent cramps. In two months the condition passed suddenly and he had almost complete relief. Approximately every six months he has had similar attacks in the legs alternately. These attacks usually followed family arguments. During one of the early attacks he had a sensation of a "loose sack about his abdomen . . . as though his shirt were hanging out." He had difficulty in retaining his stool, which was normal in consistency and frequency. He had no urinary disturbances. The attacks are sudden in onset and last from three to four weeks. He has occasional attacks of tachycardia. The present attack (four weeks in duration) involves both legs and arms, which had never been involved before. The leg symptoms are similar to those described. In the arms there is a numb sensation from the elbows down. He feels that the hands are swollen. He has trouble picking up small objects, but there is no loss of grip or strength. Sensations of heat, cold and pain are unchanged. There is no pain. The abdomen feels as though it were overloaded. He has had numerous blood Wassermann tests, all of which proved negative. He refuses to have a spinal fluid examination. There is no history of venereal infection. His wife, two children, brothers and sisters are healthy. Physically he appears to be normal. There is a slight horizontal nystagmus but the other eye signs are normal. There is no muscular atrophy. The knee jerks are markedly exaggerated. There is a spurious ankle clonus. There is no intention tremor or past pointing. The Romberg sign is negative. The Babinski reflex is present. Sensation of heat, cold, pain and position are normal. The blood count and urine analysis are normal. I believe that this is a case of early multiple sclerosis. Do you believe the history and physical signs would confirm this diagnosis? Kindly suggest a course of treatment. Please omit name.

M.D., Pennsylvania.

**ANSWER.**—This may well be a case of multiple sclerosis. Are the abdominal reflexes absent in whole or in part? Normal abdominal reflexes are unusual in cases of multiple sclerosis of long standing. There are three methods of treatment now in vogue which have been shown to be effective in many cases and also to have failed in many cases. Consequently there is no generally accepted therapeutic method. The simplest one is the administration by mouth of quinine hydrochloride in capsules in doses of 0.3 Gm. three times a day over a period of years. Richard M. Brickner has written numerous articles on this treatment, one of the recent ones appearing in the *Archives of Neurology and Psychiatry* in June 1935. The second method worthy of trial is the giving two or three times a week of intravenous injections of sodium cacodylate in increasing doses up to 1 or 1.6 Gm. Such a course of a month or two may be given during periods of exacerbation in patients who receive the quinine treatment. The third method, which is more cumbersome, is fever therapy. At the present time the induction of fever by electricity is most popular, and there has been great improvement in technic and apparatus.

#### ABORTION FOR GONORRHEA AND TUBERCULOSIS

*To the Editor:*—Would there be any danger in performing a therapeutic abortion in a patient with a two months pregnancy, acute gonorrhea and a tuberculosis of three years' duration; if so, what? Would it be safe to do a curettage on this patient? She is 23 years old. Please omit name.

M.D., Chicago.

**ANSWER.**—There would, indeed, be the greatest possible danger in the performance of a therapeutic abortion in the presence of acute gonorrhea, and the safety of a curettage on this patient would be about the same as that of smoking a cigaret over an open keg of powder.

With the patient two months pregnant, the gonorrheal infection is at least limited to the vagina and cervix and can be

appropriately and effectively treated. An ill advised attempt at abortion would be almost certain to transform this into a gonorrheal metritis with parametritis and salpingitis.

Presumably the presence of tuberculosis in the patient in question has given rise to the thought by the correspondent that the pregnancy should be interrupted; assuredly this could not have been considered on account of the gonorrheal infection. Many authorities now maintain, with statistical evidence supporting their views, that pulmonary tuberculosis does not afford a valid reason for therapeutic abortion unless the patient's condition is becoming steadily worse. The latest editions of Williams' and of De Lee's textbooks discuss this in considerable detail.

#### ULCERATIVE COLITIS IN A CHILD

To the Editor:—I should like to know what regimen you would suggest in a case of so-called idiopathic ulcerative colitis in a child of 7½ years. The patient has been in bed for almost a year, the first four months of which was spent in a well recognized hospital where repeated stool examinations and cultures revealed no specific causative organism. *Streptococcus viridans* was found and an autogenous vaccine was made but therapy with this proved of no avail. The character of the stools (pus, mucus and blood) and the roentgenologic observations together with the objective symptoms make the diagnosis certain. A typical blood count consists of 4,000,000 red cells, 15,000 white cells and 60 per cent hemoglobin. The temperature range usually is from 98.6 to 100 daily. The weight (45 pounds, or 20 Kg.) and height (48 inches, or 122 cm.) have remained about stationary for the past year. The appetite is fair. The patient is confined to bed but would be up and around if allowed to be. There are no subjective symptoms except slight pain at stool. Colonic irrigations are painful and seem to aggravate the condition, as they are always followed by an increased amount of free bright red blood in the stools. The following therapeutic measures are being carried out: 1. General diet without roughage, vegetables being puréed or put through a sieve. No meat is swallowed. Meat juice is given daily. About 1 quart of milk is consumed daily and three quarts of coffee cream weekly. 2. Irradol-A thrice daily (4 cc.). 3. Calcium lactate by mouth (30 grains, or 2 Gm., daily). 4. Liver extract (Lilly's concentrated for parenteral use) 2 cc., injected into the gluteal muscles weekly. 5. Blood transfusions (from 100 to 200 cc. of whole blood) about every six weeks or two months by the multiple syringe method. This seems to give a boost each time. Specifically, what improvement can be expected by appendectomy or appendicostomy? Kindly omit name.

M.D., District of Columbia.

ANSWER.—Chronic ulcerative colitis is a severe destructive disease of the large intestine. It should be thought of much as one thinks of tuberculosis. The immediate prognosis in this disease when it attacks a child in the first decade is not good, but slow progressive improvement usually occurs. This may take from months to years but, as a rule, unless acute recurrent infection intervenes, gradual healing of the process will usually occur under the following regimen: a generous high calory, high protein and low residue type of diet, occasional small blood transfusions, sedatives and powders as indicated, and anticolitis serum given at intervals followed by the administration of vaccine from the organisms isolated from the rectal lesions. The injections of the serum and vaccine should be continued periodically for many months. Occasionally some improvement occurs following appendicostomy, but, if surgery becomes advisable, ileostomy is the preferable procedure. Either one of these procedures may be followed by such narrowing of the bowel that the stoma may have to be a permanent one. In a child of 7½ years this is undesirable.

#### TWIN PREGNANCY WITH DEATH OF ONE FETUS

To the Editor:—There is a question in a recent issue of *THE JOURNAL* (Nov. 7, 1936, p. 1583) pertaining to twin pregnancies in which one fetus died at some time previous to the delivery of a living fetus. A similar case has recently been observed except that at about three and one-half months there was premature rupture of the membrane surrounding one fetus. An x-ray diagnosis of twins was made. The patient was very desirous of having a child and the question arose as to the possibility of her carrying the other fetus along to a viable age. The patient promptly aborted both fetuses. Can you tell me whether there is any case on record of premature rupture of membranes in a twin pregnancy at a time before viability of the fetus and subsequent growth of one or both fetuses to age of viability? Please omit name. M.D., California.

ANSWER.—Multiple pregnancy is probably more common than the recorded literature would indicate. A fetus papyraceus or compressus might be missed if the placenta and secundines are examined too carelessly. In double ovum twins, one fetus may die and be expelled, the other going normally to term. Thus M. G. Burris delivered a living female infant weighing 7 pounds (3.2 Kg.) from a woman who gave a history of having passed a fetus 3 inches long with placenta and cord attached in the third month of the same pregnancy. (Burris, M. G.: *Canad. M. A. J.* 16:170 [Feb.] 1926.)

De Lee delivered a woman at term of twins who stated that five months previously she had had an abortion of four months (De Lee, J. B.: *Principles and Practice of Obstetrics*, 1936, p. 513). Dr. T. J. Watkins (quoted by De Lee) relates the case of the delivery of twins at three months and triplets at term of the same pregnancy. Early death of one fetus may not always be followed by abortion even though the fetus becomes macerated. T. J. Parks (*Am. J. Obst. & Gynec.* 21:112 [Jan.] 1931) reports the delivery of a 1,772 Gm. fetus, 43 cm. long, in a monochorionic twin pregnancy. The other fetus was small and macerated, and both amniotic sacs were found ruptured at the time of delivery. Other cases also have been reported. When abortion of twins occurs there may even be an interval of several months between the expulsion of the first and the second fetus, as in the case cited by G. H. Schneider (*Monatschr. f. Geburtsh. u. Gynäk.* 73:5 [April] 1926).

#### ICTERUS DURING TREATMENT FOR SYPHILIS

To the Editor:—A patient was seen Sept. 4, 1936, with a primary chancre of syphilis and a 4 plus Wassermann reaction. He has received six injections of neoarsphenamine (dosage 0.6 Gm. September 8, 11, 14, 21, 28 and October 4). In addition on September 8 and 11 he received two injections of bismuth salicylate 2 grains (0.13 Gm.). Four days after the last injection of neoarsphenamine he presented himself with marked jaundice and bile in the urine. He is symptom free, as the chancre has healed, and he has never had a secondary eruption. I would appreciate your advice as to the proper drugs to use in future treatment; in other words, I would like to have a full outline as to the method of conducting treatment in face of the jaundice. The urine examination is negative. I have not done a spinal tap as yet. Please omit name if published.

M.D., New York.

ANSWER.—Icterus occurring during the course of early syphilis under treatment with the arsphenamines is by no means infrequent. It has been variously interpreted as being due to the syphilitic virus, in other words an early syphilitic hepatitis, and as being caused by the arsphenamines, owing to their destructive effect on the spirochetes in the liver. Still others, Stokes in particular, look on it as an epidemic catarrhal jaundice complicating syphilis therapy. It has also been suggested that the icterus is due to a hepatic localization of the Herxheimer reaction.

Whatever the explanation, when icterus develops during arsphenamine therapy it is wiser to discontinue the arsenical injections and give a few doses of sodium thiosulfate (1 Gm.) every other day intravenously. The diet should be a low fat, high carbohydrate diet and in severe cases hypertonic dextrose should be given intravenously in doses of from 25 to 50 cc. of a 50 per cent solution. As soon as the icterus has subsided, treatment should be cautiously resumed with bismuth preparations. Determinations of the bilirubin content of the blood by means of the van den Bergh reaction and the icterus index should be used as controls.

Milian is practically the only author who advises a continuation of arsphenamine therapy in cases of jaundice on the assumption that it is of syphilitic origin.

The danger of a possible acute yellow atrophy of the liver should be kept in mind.

#### AURICULAR FIBRILLATION

To the Editor:—A woman, aged 42, was seen by me after a three day illness complaining of marked palpitation. The heart rate was over 200 but regular. There was no objective or subjective evidence of cardiac decompensation. The blood pressure was 120 systolic, 80 diastolic. After rest, sedatives and quinidine in 6 grain (0.4 Gm.) doses daily the heart rate slowed down to 100 but is totally irregular. Use of digitalis with subsequent quinidine administration and administration of the two together has failed to correct the auricular fibrillation (which I presume it is). There is present a mitral systolic murmur. The heart is not enlarged by percussion. The patient is comfortable. The patient was examined eight years ago and passed for life insurance and has had no illnesses or any rheumatic manifestation. The basal metabolic rate is plus 6. What is the cause of the irregularity? Is digitalis indicated? What can be done to correct the cardiac irregularity? Kindly omit name.

M.D., New York.

ANSWER.—The onset of auricular fibrillation may be preceded by rapid, regular pulse. An auricular fibrillation with a rate of 200 may appear regular. Digitalis is indicated only to control the rate of the heart and to maintain the heart rate at a level that gives the best clinical response.

An attempt can be made to restore the heart to a normal mechanism by means of quinidine, or the rate can be controlled indefinitely by means of digitalis in proper dosage. It is not so much the auricular fibrillation that is a mechanical deterrent as it is the rapid rate which accompanies it and which results in a decreased minute volume of blood being delivered by the heart.

## Medical Examinations and Licensure

### COMING EXAMINATIONS

#### STATE AND TERRITORIAL BOARDS

**ALASKA:** Juneau, March 2. Sec., Dr. W. W. Council, Juneau.

**ARIZONA:** Phoenix, Jan. 5-6. Sec., Dr. J. H. Patterson, 826 Security Bldg., Phoenix.

**CALIFORNIA:** *Reciprocity.* San Francisco, Jan. 6. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

**COLORADO:** Denver, Jan. 5. Sec., Dr. Harvey W. Snyder, 422 State Office Bldg., Denver.

**CONNECTICUT:** *Basic Science.* New Haven, Feb. 13. *Prerequisite to license examination.* Address State Board of Healing Arts, 1895 Yale Station, New Haven. *Medical (Homoeopathic).* Derby, Feb. 13. Sec., Dr. Joseph H. Evans, 1488 Chapel St., New Haven. *Medical (Regular).* Hartford, March 9-10. *Endorsement.* Hartford, March 23. Sec., Dr. Thomas P. Murdock, 147 W. Main St., Meriden.

**DISTRICT OF COLUMBIA:** Washington, Jan. 11-12. Sec., Commission on Licensure, Dr. George C. Ruhland, 203 District Bldg., Washington.

**IDAHO:** Boise, April 6. Commissioner of Law Enforcement, Hon. Emmitt Pfost, 205 State House, Boise.

**ILLINOIS:** Chicago, Jan. 26-28. Superintendent of Registration, Department of Registration and Education, Mr. Homer J. Byrd, Springfield.

**INDIANA:** Indianapolis, June 22-24. Sec., Board of Medical Registration and Examination, Dr. William R. Davidson, 301 State House, Indianapolis.

**IOWA:** *Basic Science.* Des Moines, Jan. 12. Sec., Prof. Edward A. Benbrook, Iowa State College, Ames.

**MAINE:** Portland, March 9-10. Sec., Board of Registration of Medicine, Dr. Adam P. Leighton, 192 State St., Portland.

**MINNESOTA:** *Basic Science.* Minneapolis, Jan. 5-6. Sec., Dr. J. Charnley McKinley, 126 Millard Hall, University of Minnesota, Minneapolis. *Medical.* Minneapolis, Jan. 19-21. Sec., Dr. Julian F. Du Bois, 350 St. Peter St., St. Paul.

**MONTANA:** Helena, April 6. Sec., Dr. S. A. Cooney, 7 W. 6th Ave., Helena.

**NEBRASKA:** *Basic Science.* Omaha, Jan. 12-13. Director, Bureau of Examining Boards, Mrs. Clark Perkins, State House, Lincoln.

**NEVADA:** *Reciprocity.* Carson City, Feb. 1. Sec., Dr. John E. Worden, Carson City.

**NEW HAMPSHIRE:** Concord, March 11-12. Sec., Board of Registration in Medicine, Dr. Charles Duncan, State House, Concord.

**NEW MEXICO:** Santa Fe, April 12-13. Sec., Dr. Le Grand Ward, Box 693, Santa Fe.

**NEW YORK:** Albany, Buffalo, New York and Syracuse, Jan. 25-28. Chief, Professional Examinations Bureau, Mr. Herbert J. Hamilton, 315 Education Bldg., Albany.

**NORTH DAKOTA:** Grand Forks, Jan. 5-8. Sec., Dr. G. M. Williamson, 4½ S. 3rd St., Grand Forks.

**OREGON:** Portland, Jan. 5-7. Sec., Dr. Joseph F. Wood, 509 Selling Bldg., Portland.

**PENNSYLVANIA:** Philadelphia, Jan. 5-9. Sec., Board of Medical Education and Licensure, Mr. James A. Newpher, Education Bldg., Harrisburg.

**PUERTO RICO:** San Juan, March 2. Sec., Dr. O. Costa Mandry, Box 536, San Juan.

**RHODE ISLAND:** Providence, Jan. 7-8. Chief, Division of Examiners, Mr. Robert D. Wholey, 366 State Office Bldg., Providence.

**SOUTH DAKOTA:** Pierre, Jan. 19-20. Dir., Division of Medical Licensure, Dr. B. A. Dyar, Pierre.

**VERMONT:** Burlington, Feb. 10-12. Sec., Board of Medical Registration, Dr. W. Scott Nay, Underhill.

**WASHINGTON:** *Basic Science.* Seattle, Jan. 7-8. *Medical.* Seattle, Jan. 11-13. Dir., Department of Licenses, Mr. Harry C. Huse, Olympia.

**WEST VIRGINIA:** Charleston, March 1. Sec., Public Health Council, Dr. Arthur E. McClue, State Capitol, Charleston.

**WISCONSIN:** Madison, Jan. 12-14. Sec., Dr. Henry J. Gramling, 2203 S. Layton Blvd., Milwaukee.

**WYOMING:** Cheyenne, Feb. 1. Sec., Dr. G. M. Anderson, Capitol Bldg., Cheyenne.

#### NATIONAL BOARD OF MEDICAL EXAMINERS

**NATIONAL BOARD OF MEDICAL EXAMINERS:** *Parts I and II.* Feb. 9-11, May 10-12, June 21-23, and Sept. 13-15. *Part III.* New York, Jan. 11-13 and Chicago, Jan. 19-21. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

#### SPECIAL BOARDS

**AMERICAN BOARD OF INTERNAL MEDICINE:** *Written examination will be held simultaneously in different centers of the United States and Canada in March. Practical examination will be given in St. Louis in April and at Philadelphia in June.* Chairman, Dr. Walter L. Bierring, 406 Sixth Ave., Rm. 1210, Des Moines.

**AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY:** *Written examination for Group B applicants will be held in various cities throughout the United States and Canada, March 6. Practical, oral and clinical examinations for Group A and B applicants will be held at Atlantic City, N. J., June 7-8. Applications must be received at least sixty days prior to the examination dates.* Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh (6).

**AMERICAN BOARD OF OPHTHALMOLOGY:** Los Angeles, Jan. 23. Sec., Dr. John Green, 3720 Washington Blvd., St. Louis, Mo.

**AMERICAN BOARD OF ORTHOPAEDIC SURGERY:** Cleveland, Jan. 9. Sec., Dr. Fremont A. Chandler, 180 N. Michigan Ave., Chicago.

**AMERICAN BOARD OF OTOLARYNGOLOGY:** Philadelphia, June 7-8. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

**AMERICAN BOARD OF PATHOLOGY:** Chicago, March 26-27. Sec., Dr. F. W. Hartman, Henry Ford Hospital, Detroit, Michigan.

**AMERICAN BOARD OF PEDIATRICS:** New York, Jan. 23. Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Illinois.

### West Virginia October Report

Dr. Arthur E. McClue, secretary, West Virginia Public Health Council, reports the oral and written examination held in Wheeling, Oct. 12-14, 1936. The examination covered 11 subjects and included 110 questions. An average of 80 per cent was required to pass. Fourteen candidates were examined, all of whom passed. Nine physicians were licensed by reciprocity and 1 physician was licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Howard University College of Medicine.....	(1935)		87.3
Northwestern University Medical School.....	(1935)		89.3
New York University, University and Bellevue Hospital Medical College.....	(1934)		90.3
Duke University School of Medicine.....	(1933)		85.1
University of Cincinnati College of Medicine.....	(1935)		85.3
Hahnemann Medical College and Hosp. of Philadelphia.....	(1935)		84.1
Jefferson Medical College of Philadelphia.....	(1935)		87.8, 90.7
Medical College of Virginia.....	(1934)	88.2, (1935)	86.3, 87.2
University of Virginia Department of Medicine.....	(1928)		88.3
(1934)	89.6, (1935)		83.7

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
University of Maryland School of Medicine and College of Physicians and Surgeons.....	(1935)		Maryland
University of Michigan Medical School.....	(1932)		Penna.
Washington University School of Medicine.....	(1934)		Missouri
Ohio-Miami Medical College.....	(1913)		Ohio
Western Reserve University School of Medicine.....	(1934)		Ohio
University of Oklahoma School of Medicine.....	(1931)		Oklahoma
Temple University School of Medicine.....	(1934)		Penna.
Medical College of Virginia.....	(1911)		Virginia
University of Virginia Department of Medicine.....	(1932)		Virginia

School	LICENSED BY ENDORSEMENT	Year Grad.	Endorsement of
Harvard University Medical School.....	(1934)		N. B. M. Ex.

### Wisconsin Reciprocity Report

Dr. Henry J. Gramling, secretary, Wisconsin State Board of Medical Examiners, reports 11 applicants licensed by reciprocity at the meeting held at Madison, September 8, 1936. The following schools were represented:

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
Loyola University School of Medicine.....	(1932)		Illinois
Indiana University School of Medicine.....	(1930)		Indiana
State University of Iowa.....	(1932)		Iowa
University of Louisville.....	(1934)		Minnesota
Tulane University of Louisiana.....	(1915)		Louisiana
University of Minnesota.....	(1935)		Minnesota
Columbia University College of Physicians and Surgeons.....	(1932)		New York
Ohio State University College of Medicine.....	(1931)		Ohio
University of Wisconsin Medical School.....	(1927)		Michigan
Osteopath*.....			Illinois

\* Licensed to practice osteopathy and surgery.

### Indiana June Examination

Dr. William R. Davidson, secretary, Indiana State Board of Medical Registration and Examination, reports the written examination held in Indianapolis, June 23-25, 1936. The examination covered 15 subjects and included 100 questions. One hundred and eighteen candidates were examined, all of whom passed. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Loyola University School of Medicine.....	(1936, 5),*	(1936)	84.9
University of Illinois College of Medicine.....	(1934)		82.4

## Book Notices

**A Text-Book of Pharmacology and Therapeutics or the Action of Drugs in Health and Disease.** By Arthur R. Cushny, M.A., M.D., LL.D. Eleventh edition, revised by C. W. Edmunds, A.B., M.D., Professor of Materia Medica and Therapeutics and Director of the Pharmacological Laboratories in the University of Michigan, Ann Arbor, and J. A. Gunn, M.A., M.D., D.Sc., Professor of Pharmacology and Director of the Nuffield Institute for Medical Research, University of Oxford, Oxford, England. Cloth. Price, \$6.50. Pp. 808, with 70 illustrations. Philadelphia: Lea & Febiger, 1936.

To keep a textbook on pharmacology down to date requires arduous work on the part of the authors. Not only must the authors be abreast of the increasing fund of knowledge related to drugs and their actions but the book must be brought into conformity with the ever changing standards of official compendiums such as the U. S. Pharmacopeia and the British Pharmacopeia. Since the decennial revisions of official books of standards became official this year, nearly every book dealing with official medicaments has undergone a revision. Cushny's *Pharmacology and Therapeutics* by Edmunds and Gunn is subject to increasing watchfulness because it covers not only the drugs of the United States but those standardized in the British empire. The 1936 revision has been thorough. Not only has the text been revised but there has been a noticeable rearrangement of the order of the book and discussions of the subjects. In this arrangement the idea has been that the simpler substances should be discussed first, leaving the more complex considerations toward the latter part of the book, though no didactic rule could be made. In common with most pharmacologies, it is necessary to have an introduction to the field of pharmacology and its definitions so that the student or consultant may interpret better the technical discussions.

To one who has followed the development of textbooks on pharmacology it is noted that therapeutics has been changing, particularly in the last few years, by intensive study of those extremely active substances which are loosely classified as vitamins, hormones or glandular principles. Twenty years ago almost no mention was made of liver and liver preparations; today they form an important part of *materia medica*. The same is true of the vitamins, which require approximately fourteen pages for a limited discussion by Edmunds and Gunn. Also noticeable is the much better understanding of glandular therapy today, as is evidenced by the technical discussions in pharmacologies. And yet these discussions cannot help but be simply epitomizations of the knowledge that is required for scientific clinical practice.

A particularly valuable discussion by the authors is that on the opium series. Space does not permit critical comment of many of the excellent chapters contained in this book. There is, however, one criticism to be made—the index is hardly ample for a book containing as much useful information as Cushny's *Pharmacology*. In accord with previous editions, the book is printed on excellent paper and the typographical setup is inviting. The bibliographies of the discussions, while ample, are not extensive. The book is one that will continue to receive recognition both in Great Britain and in the United States.

**Techniques chirurgicales.** Publiées par A. Gosset, chirurgien de la Salpêtrière. Avec la collaboration de L. G. Amlot, et al. Cloth. Price, 125 francs. Pp. 436, with 22 illustrations. Paris: Masson & Cie, 1936.

Of late there has been a tendency to group the works of many under the editorship of one individual. Gosset assumes such a rôle in this work. The book is divided into fifteen chapters. While it is not a manual for the student, it affords excellent reading for the experienced surgeon. Gosset's collaborators work at the Salpêtrière, where he has been director for the last twenty years. Much space is devoted to organization and hospital methods, sterilization, equipment, architecture of the pathologic and anatomic laboratories, the library and the operating room. It concludes with a roster of the surgeons and their assistants. It also carries the announcement that Dr. Le Noir, member of the Academy of Medicine and honorary physician of the hospitals, conducts in Gosset's service consultations in gastro-enterology, "meticulously carried out." Custom and taste obviously differ among men of science in various habitats. A great deal of space (more than a hundred

pages) is devoted to the details of sterilization and the biochemistry of anesthesia.

Petit-Dutailis contributes a chapter on neurotomy of the trigeminus through a posterior approach, which is written lucidly and is illuminatingly illustrated by Frantz, who created for himself an enviable reputation as a medical illustrator. His fine work is in decided contrast to the photography in the preliminary chapters, which is rather inferior. Sauvage and Wallon point out, as the result of an intensive study, that a combination of surgery and radium in cases of cancer affecting the upper jaw is effective, if attacked early. They stress the importance of early diagnosis and counsel that serious consideration be given to such apparently simple manifestations as nasal discharge, toothache and persistent sinusitis, which may all be telltale symptoms of an early carcinoma of that region. In their series of cases (many were desperate) they were able to observe successful results from three to ten years in nine instances. "If that is so," ask the authors, "how much better results may one expect in cases which are diagnosed early and promptly subjected to treatment." Soupault (chapter 7) discusses diaphragmatic hernia but offers nothing of a departure from the standard methods now in vogue. Charrier (chapter 8) describes gastrectomy as related to gastrojejunal ulcer. It is well illustrated, as is the succeeding chapter on gastrectomy for carcinoma by Georges Loewy. Gosset contributes chapter 10, on appendicitis. He uses the McBurney incision, which in certain quarters in England is being abandoned in favor of the pararectus approach. Gosset discusses indications for operative intervention in an excellent manner. He stresses what he stressed some thirty years ago: "My formula is simple," says Gosset; "operate always and operate promptly." He has no patience with procrastination, no matter under what form. Where expectancy seems indicated, his advice recalls the aphorism of Hamilton Bailey to "practice expectancy at the door of the operating theater." Again while the pendulum is still swinging on the question whether to drain or not to drain in appendicitis, Gosset justly reminds us that there exists no universal formula—that cases for drainage or those not to be drained must be selected; yet in every case of doubt "I drain," says Gosset, adding "What disadvantages can there come from drainage? These are certainly minor, but in certain cases the absence of a drain may spell death." To this dictum one may wholeheartedly subscribe. Another advantage of drainage, in the sense of Gosset, besides permitting septic material to find its way to the surface, is that the opening through which the drain emerges may be used to introduce antigangrenous and anticolibacillary serum, which when introduced intramuscularly are not as effective as when injected through the opening created by the drain. In cases of diffuse peritonitis, Gosset counsels counter drainage through the left iliac fossa; he reminds us that, in the iliac forms of appendicitis attended by much suppuration and operated on late, "one cannot always present the patient with the appendix." This chapter concludes with the treatment of right inguinal hernia with complementary appendectomy.

Intestinal obstruction, to which surgeons are paying much just attention of late, is ably discussed by Ledoux-Lebard, Thalheimer and Garcia-Calderon. These authors stress the importance of early diagnosis and depend mainly on radiology and the barium sulfate enema for the localization of the seat of obstruction. The chapter is illustrated by roentgenograms and concludes with indications for operative intervention. No mention is made of abdominal auscultation, so important a diagnostic medium according to certain American surgeons. Carcinoma of the large bowel claims the greater part of the remaining text. Right hemicolectomy is discussed by Gosset and illustrated by Frantz; carcinoma of the left colon is discussed by Ledoux-Lebard. In English literature exteriorization procedures are usually credited to Paul-Mikulicz; here Bloch's name is substituted for that of Paul. It seems that Bloch has preceded Paul in the thought of exteriorization of the bowel in carcinoma of the left colon, while Mikulicz, according to the late Lord Moynihan, contributed nothing original to the subject other than elaborating on the ideas of his predecessors. Fred Rankin is justly mentioned with reference to some technical details connected with operations on carcinoma of the colon. The importance of cecostomy is

stressed. The description of the procedure is graphic, thorough and painstaking. The illustrations are equally good. A clamp applied to the cecum to avoid soiling, while mentioned in the text, is not shown in the illustration; while this is not a serious omission to the advanced surgeon, it certainly is of utmost importance for the beginner. The other steps of the operation are well illustrated. The final chapters are devoted to a discussion on the results obtained from treating fibroids of the uterus surgically by Gosset and Funck-Brentano, and the treatment of complicated fractures of the ankle, by Guy Seille. A bibliography is attached to each chapter.

**Skyways to a Jungle Laboratory: An African Adventure.** By Grace Crile. Cloth. Price, \$2.75. Pp. 240, with 51 illustrations. New York: W. W. Norton & Company, Inc., 1936.

Mrs. Crile describes the journey from London to Nairobi by Imperial Airways—except from Paris to Brindisi—and adventures in connection with a "jungle" laboratory situated "in the richest territory in the world for abundance and variety of animal life." The first fifty pages are concerned with the journey to Nairobi and are replete with information on the country covered. The author, an intelligent observer, knows what she sees, whether on land or water, so that her descriptions are both interesting and informing. The journey from London to Khartoum may be regarded as within the borders of civilization, since Khartoum can be reached by rail and is attracting tourists. But what of the trip from Khartoum to Nairobi through much of darkest Africa? It took two days and a night. What about food and sleep? A few quotations will answer the questions:

Malakal: From the Grand Hotel at Khartoum "the plane was off at 6:40 a. m. . . . reached Malakal at 10:30. . . . The tall native chief broke a hole in each petrol tin with a big ugly knife, natives swarmed around to watch, and we were refueled. Meanwhile we were invited into a cool, screened tent for lunch. Here tables were spread and delicious Nile fish, potatoes, beans, a complot of mixed canned fruit and coffee were served on pretty Airways china. This is England—off at the end of nowhere."

Juba for the night: "We arrived at Juba about 3 o'clock in time for tea on the veranda. . . . The bedrooms were prettily furnished . . . each has a screened porch . . . electric fan. We luxuriated in hot baths. . . . During dinner a radio played in the next room and we heard quotations of the various stockmarkets, so we are not so far away from everywhere after all."

Entebbe: "It was still dark when we climbed into the plane (at Juba) with promise of breakfast at Entebbe some 340 miles on. . . . We breakfasted at nine on luscious pineapple, the best little finger-long bananas I ever ate, bacon, eggs, sausages and coffee. The hotel was clean and attractive."

Kisumu: "We stopped at Kisumu for breakfast. Apparently everything one plants at Kisumu grows. There were flowers of the most gorgeous hues all around the hotel."

As Nairobi is reached in two or three hours after one leaves Kisumu it is quite evident that "Skyways" over Africa entails no hardships; rather it would seem that this would be a fine pleasure trip. From Nairobi to "Journeys end," which means Maji Moto Camp, was by plane and automobile. "Maji Moto Camp consists of fourteen native huts built of mud, reed and bamboo, and thatched with straw, encircling a large ring where the fire burns at night and two boys stand guard. We are  $3\frac{1}{2}$  degrees south of the equator. The altitude is about 4,000 feet. Here night falls like a curtain. At five minutes of six it is light. At five minutes past six it is night." One of these huts became the "Jungle Laboratory." The staff consisted of Dr. and Mrs. Crile; Daniel P. Quiring, Ph.D., of the department of biology of Western Reserve University; A. B. Fuller, chief preparator of the Cleveland Museum of Natural History; Dr. W. H. Carr, a young English physician who went out to hunt but joined the group and assisted in the dissections; Bryan Cooper, a biologist, and Captain J. R. Hewett. In the division of the work Mrs. Crile was allotted the task to "weigh the organs and keep the records."

Animals dissected ranged from the elephant, rhino and hippo down to the innocent little dik dik. Of course it was necessary to catch and kill the animal before it could be dissected. Here is where the sport came in—a sport which supplied plenty of adventures and not a little danger. These, the adventures and dangers, the author has here recorded in a manner which, if equaled by her records of the dissections, will make the latter delightful reading. One hundred and fifty original photographs, many in group pictures, practically all taken by members of the staff, add interest and value to the book.

**Pédiatrie pratique. Répertoire de mises au point. Indications et moyens thérapeutiques.** Par Eugène Terrien. Paper. Price, 24 francs. Pp. 247. Paris: Masson & Cie, 1936.

This paper bound volume is in no sense a textbook, being more a brief outline of methods of treatment recently employed in the various ailments of children. The diseases or syndromes are arranged in alphabetical order. Usually little more than a page is given to any particular disorder, the discussion being limited to a brief description of the nature of the disease, occasionally a word as to its etiology or symptomatology, one or more brief paragraphs on treatment, usually including suggestions from a number of writers, and finally a terse conclusion. Some of the treatment recommended varies considerably from that employed in this country. In acrodynia, acetylcholine and the x-rays are recommended. In adiposogenital dystrophy, anti-syphilitic treatment has at times been highly successful. In severe tonsillitis and pharyngitis, irrigation of the throat with seltzer water gives relief. For the practitioner of pediatrics, the book has some value. Its convenient arrangement and form as well as its brief but definite suggestions make it a concise little guide. The busy practitioner may in a few moments review the newest ideas in treatment and may at times find methods that are new to him.

**A Text-Book of Physiology.** By H. E. Roaf, M.D., D.Sc., M.R.C.S., Professor of Physiology in the University of Liverpool. Second edition. Cloth. Price, \$6.75. Pp. 679, with 338 illustrations. Baltimore: William Wood & Company, 1936.

This book is meant for medical students and others taking a first comprehensive course in physiology. As such it is a reasonably satisfactory work. It treats all the major fields of the subject and gives a great deal of information, though not always with a great deal of critical acumen. For example, it is stated categorically, and a chemical equation is written purporting to show, that the gastric hydrochloric acid is derived from a reaction between sodium chloride and carbonic acid.

A beginning student could scarcely be blamed for interpreting that statement literally. Another example of this type of defect appears in the last chapter, on emotional reactions. Here the ideology of psychoanalysis is freely, and without critical comment, incorporated as physiologic dogma. The assumption, for example, of a "censor" for an extensive subconscious mind is not based on acceptable scientific data and does not deserve unqualified acceptance in a teaching textbook of physiology. Other unjustifiable tacit assumptions greatly detract from the value of this portion of the book, although it must be admitted that the incorporation of some experimental psychology is in itself a real asset. These criticisms should not be taken to imply that there are not valuable sections in the book. The first chapter gives an excellent elementary account of the mechanics of posture and movement.

**New and Nonofficial Remedies, 1936, Containing Descriptions of the Articles Which Stand Accepted by the Council on Pharmacy and Chemistry of the American Medical Association on January 1, 1936.** Cloth. Price, \$1.50. Pp. 542. Chicago: American Medical Association, 1936.

The appearance of the U. S. P. XI made necessary an extensive revision of the 1936 edition of New and Nonofficial Remedies. This seems somewhat paradoxical in view of the name of the Council's valuable book. But the fact is that there have always been included in New and Nonofficial Remedies a great many official drugs. Manufacturers apparently have appreciated the distinction given their brands by Council acceptance, and the public and the medical profession have certainly benefited by the Council's supervision of advertising claims for products the fundamental value of which has already been established. Of the fifty-four therapeutic agents added to the Pharmacopeia, forty-one are nonofficial preparations stood accepted for New and Nonofficial Remedies. The following is a list of the former N. N. R. preparations that are now official in the Pharmacopeia (the new pharmacopeial name is given): Acriflavine, Acriflavine Hydrochloride, Ethylene, Ethylhydrocupreine Hydrochloride, Scarlet Fever Antitoxin, Bismuth and Potassium Tartrate, Calcium Creosote, Calcium Gluconate, Chlorbutanol, Emulsion of Liquid Petrolatum, Ephedrine, Ephedrine Hydrochloride, Ephedrine Sulfate, Diluted Erythritol Tetranitrate, Extract of Liver, Green Iron and Ammonium Citrates, Soluble Fluorescein, Mercuric Succinimide, Iodo-

phthalein, Solution of Irradiated Ergosterol, Solution of Liver, Purified Solution of Liver, Solution of Parathyroid, Merbaphen, Neocincophen, Iodized Oil, Phenacaine Hydrochloride, Soluble Phenobarbital, Chiniofon Powder, Antimeningococcic Serum, Antipneumococcic Serum, Type I, Stomach, Theophylline with Ethylene Diamine, Theophylline with Sodium Acetate, Diphtheria Toxoid, Diphtheria Toxin for the Schick Test, Scarlet Fever Streptococcus Toxin, Tryparsamide, Old Tuberculin, Rabies Vaccine, Bacterial Vaccine made from the Typhoid Bacillus, Bacterial Vaccine made from Typhoid Bacillus and the Paratyphoid A and B Bacilli.

In most cases the New and Nonofficial Remedies tests and standards were taken over in whole or in part by the Pharmacopeia. This is eloquent evidence of the wisdom of the Council's selections since the appearance of the U. S. P. X.

Among the new products described in this edition of New and Nonofficial Remedies are Isopropyl Alcohol, Aminoacetic Acid, Larocaine Hydrochloride, Alurate and Sodium Alurate, Ipral Sodium, Ephedrine Hemihydrate, Azochloramid, Beta-Lactose, Pyrethrum Ointment, Meningococcus Antitoxin and Staphylococcus Toxoid.

Noteworthy revisions have been made of the chapters on Bismuth Compounds, Organs of Animals and Serums and Vaccines. These annual revisions place each succeeding edition of New and Nonofficial Remedies in a class by itself as an authoritative guide to therapeutic progress.

**Sport- und Arbeitsschäden: Eine Zusammenfassung klinischer Beobachtungen und wissenschaftlicher Erkenntnisse zur Biologie der Arbeit und Pathologie der Funktion.** Von Wilhelm Baetzner, Direktor der 3. Chirurgischen Universitätsklinik im Städtischen Robert-Koch-Krankenhaus, Berlin. Mit einem Geleitwort von Professor August Bier. Im Jahre der XI. Olympischen Spiele 1936. Paper. Price, 8 marks. Pp. 136, with 133 illustrations. Leipzig: Georg Thieme, 1936.

The theme of this book is that sports should be used to strengthen and develop the body, as one might use medicine, and not overdone for the sake of records that demand using the last strength with the last breath. In Germany there is a tendency to overemphasize athletics for the sake of making new records and winning contests, as notably the Olympic games. Overtraining and overexertion are a detriment to physical development and well being. Generalized sports are not good for every one. Sports demand motions foreign to joints and organs. Athletic injuries are similar to industrial injuries, but the latter never demand overstrain except in the continued use of one set of muscles in certain types of work. Athletes are more prone to infection and their cuts, bruises and injured bones do not heal so well as other injuries. Athletes are often poor workers and cannot do good brain work when exercising too much. Hard exercise depresses the glandular activity and lessens the birth rate. A woman active in sport rarely brings up a child, and males have fewer offspring. Champion athletes, e.g., Cambridge and Oxford oarsmen, usually do not amount to much in life, are weak and die early. Pneumonia kills many athletes. Hypertrophied organs disturb the mutual relation of the organs. The proper athletics should be good for every one and not be reserved for a privileged class of good athletes. Properly indulged in, sports should improve the general health. Severe recreational exercise should not be combined with heavy work, but a brain worker should take up a sport. Critics have attacked this theory, especially coaches and athletes. A habitual athlete receives severe injuries as a result of his overactivity. Many so-called injuries are the result of damage from prolonged indulgence or overstrain. The author cites many illustrations of these injuries, including a javelin thrower whose humerus fractured while throwing, and a football player who fractured his femur while in the air. Tabler quotes observations on 1,400 Swiss mountaineers in whom injuries to the meniscus showed premature degeneration due to abnormal use of knees in the mountains. Many joints showing degenerative and proliferative changes, loose bodies and spurs are cited. Osteochondritis dissecans is shown in the knee, hand, wrist, foot, ischium and elbow. Bone changes occur, fractures, osteoporosis, split patellae, degenerative changes as in tibial tubercle, the navicular bone, the metatarsals, split fibulae and osseous proliferation. Injuries in the muscles, tendons and ligaments are illustrated. The illustrations are excellent, showing a great

variety of roentgenograms illustrating the different lesions. The book is well written and typically German in that it takes up the etiology and pathology rather exhaustively and says practically nothing about treatment. The multiplicity of examples and the redundant repetition of the main theme are calculated to impress the point on even the most ponderous of Teutonic intellects.

**Materia Medica and Therapeutics: A Text-Book for Nurses.** By Linette A. Parker, B.Sc., R.N. Sixth edition. Cloth. Price, \$2.50. Pp. 377, with 35 illustrations. Philadelphia: Lea & Febiger, 1936.

In a book that gives so much that is practical in so small a space, much has to be forgiven. There is no doubt that it fills the needs for which it is designed as well as and perhaps better than some other books on the subject. It would be desirable, however, if a person who teaches this subject and especially one who writes on it were somewhat better grounded in pharmacology than the author seems to be. Thus to mention strychnine as a true heart stimulant or to consider morphine and bromides as heart depressants is not in line with modern teaching. However, it probably does not do much harm, as professional ethics requires nurses to receive opinions respectfully on the action of drugs expressed by doctors who are not much better grounded in their knowledge of pharmacology.

**Fundamentals of Human Physiology.** By the late J. J. R. MacLeod, M.B., D.Sc., F.R.S., and R. J. Seymour, M.S., M.D., Professor of Physiology, Ohio State University, Columbus, Ohio. Fourth edition. Cloth. Price, \$2.50. Pp. 424, with 108 illustrations. St. Louis: C. V. Mosby Company, 1936.

This first venture into the field of authorship by a man whose major interest for many years has been the teaching of elementary physiology to college students is a well arranged and constructed textbook in which the good features of earlier editions have been retained and amplified on the basis of the author's experience in this particular field. Experience in teaching elementary physiology motivates a general criticism, which applies to most elementary textbooks on physiology; namely, too great a degree of attenuation of factual material and too little effort to apply facts to everyday life. A student in a course to which this textbook is applicable will in most instances never go any further in the study of physiology. It is all the more important, therefore, that every possible application be made to circumstances of living. This textbook fails largely to accomplish this end except in a brief appendix on public and personal hygiene devoted to communicable diseases, industrial hygiene, sewage disposal, water and food, hygiene of excretion, ventilation, hygiene of the nervous and muscular systems and child hygiene, but the discussion is too brief even to stimulate the student to further inquiry. There is an excellent glossary of physiologic terms, which should be a valuable aid to the beginning student. Some of the illustrations are poorly reproduced, such as figures 28, 42, 43, 45, 46, 64, 65, 66, 67, 68, 69, 70 and 89; pen drawings, color plates and diagrams are, however, well reproduced and are in general well selected. The sections on endocrines and vitamins are inadequate as to both content and presentation. The revising author has to a considerable degree failed to take advantage of an opportunity to make the subject of physiology live for the most eager and enthusiastic class of students of the subject, namely, those who elect to take the course for the sake of their own general enlightenment.

**Fisiopatologia della ghiandola pineale.** Dal Dott. Francesco Molino, assistente nell'Istituto di clinica medica della R. Università di Genova. Paper. Price, 15 lire. Pp. 135, with illustrations. Rome: Luigi Pozzi, 1935.

This Italian monograph on the pineal body will be of interest to American readers chiefly by reason of its extensive bibliography, which includes over 300 references. The literature is covered to 1934; more recent publications of Engel, Saphir, Rowntree and his collaborators and other workers on the physiologic effects of pineal extracts are therefore not considered. The author presents brief summaries of knowledge of the pineal gland from many aspects, historical, phylogenetic, anatomic, histologic and physiologic, the latter including what little is known of its endocrine function and its functional relation to other organs.

Methodik der medizinischen Erbforschung unter besonderer Berücksichtigung der Psychiatrie. Von Dr. Bruno Schulz, Assistent am Kaiser Wilhelm-Institut für Genealogie und Demographie der Deutschen Forschungsanstalt für Psychiatrie in München. Paper. Price, 10.50 marks. Pp. 189, with 16 illustrations. Leipzig: Georg Thieme, 1936.

This is an extremely technical work concerning methods of handling statistical data on heredity. There are numerous mathematical equations, which a clinician will have difficulty grasping. The conclusions regarding the rôle of heredity in the production of psychoses are dealt with elsewhere. The book represents the technical attitude of the workers in the Munich institute toward the general problem. Once the material is obtained, it is probably satisfactorily handled mathematically. The clinician, however, wonders about the accuracy of diagnosis, the type of clinical records and the longitudinal studies of individual patients as they may affect the stuff with which the statistician deals.

## Bureau of Legal Medicine and Legislation

### MEDICOLEGAL ABSTRACTS

**Health Insurance: Disability Due to Myocarditis Resulting from Pneumonia.**—The defendant insurance company agreed to pay certain benefits to the plaintiff if he became disabled. Liability was limited to a maximum period of six weeks if he became disabled because of "any chronic or recurring disease." The plaintiff had pneumonia, which resulted in myocarditis from which disability ensued. The insurance company refused to pay more than the limited benefits provided in the policy. The plaintiff therefore sued and obtained judgment, from which the company appealed to the Supreme Court of Appeals of West Virginia.

The insurance company contended that since the plaintiff's disability was caused by a "chronic or recurring disease," myocarditis, he was entitled only to the limited benefits. The plaintiff protested that even though myocarditis is a "chronic or recurring disease" his disability actually grew out of his original illness, pneumonia, and that he was entitled to the full benefits provided by the policy. If, said the Supreme Court of Appeals, the meaning of the language of an insurance policy is in doubt, it should be construed favorably to the insured. In the present case, the insurance company assumed the risk of illness from pneumonia and also the risk of all the direct results of that disease. The circumstance that pneumonia directly resulted in a condition that could be described as another and different disease makes no difference. As long as it is a condition definitely attributed to the occurrence of the risk insured against, the fact that its severity may justify classifying it as an independent disease is not a determining factor. The insured undoubtedly had pneumonia and the pneumonia undoubtedly caused the heart condition that compelled him to give up his work. The plaintiff was therefore entitled to the maximum benefits provided by the policy. Judgment in favor of the plaintiff was affirmed.—*White v. Inter-Ocean Casualty Co. (W. Va.)*, 185 S. E. 203.

**Accident Insurance: "Death Resulting from Accidental Suffocation by Gases" Construed.**—The defendant insurance company issued to the insured two accident insurance policies in which it promised to pay certain benefits in case the insured died but limited liability to \$600 in event of "death resulting from accidental suffocation by illuminating or other gases or the accidental taking of any poison." Three days after the policies were issued, the insured was found in his garage overcome by the fumes escaping from the motor of his automobile. He died a few minutes later from carbon monoxide poisoning. The defendant claimed that the death resulted "from accidental suffocation by illuminating or other gases" and that therefore it was liable only to the extent of \$600. The plaintiff, the beneficiary under the policies, brought suit to recover the maximum benefits. The trial court sustained the defendant's motion to withdraw from the jury the question of liability over and above \$600 and, with the consent of the defendant,

entered a judgment for the plaintiff for that amount. The plaintiff thereupon appealed to the Supreme Court of Nebraska.

It was not disputed, said the court, that the insured died as a result of his inhaling the fumes from the exhaust of his automobile. That the death was therefore caused by the inhalation of gas cannot be denied. In *Birss v. Order of United Commercial Travelers*, 109 Neb. 226, 190 N. W. 486, it was said:

The term "gas" is, in a sense, a generic term and is broad and sweeping in its meaning. In Webster's Unabridged Dictionary it is defined as "an aeriform fluid; a term used at first by chemists as synonymous with air, but since restricted to fluids supposed to be permanently elastic, as oxygen, hydrogen, etc., in distinction from vapors, as steam, which become liquid on a reduction of temperature. In present usage, since all of the supposed permanent gases have been liquefied by cold and pressure, the term has resumed nearly its original significance, and is applied to any substance in the elastic or aeriform state."

The contention of the beneficiary was that death had not resulted from accidental suffocation, relying apparently on medical testimony to the effect that inhaled carbon monoxide gas does not stay in the lungs and does not therefore act as a mechanical barrier to respiration. Death results when there is sufficient concentration of carbon monoxide combined with the hemoglobin or red blood cells to displace the oxygen. But, said the court, in construing the contract of insurance, words used therein will be considered as used in their ordinary and popular sense. The definitions or constructions placed on them by the scientist or expert cannot control. "Suffocate," continued the court, is defined in Webster's New International Dictionary as "to kill by stopping respiration, as by strangling or asphyxiation," while the same authority defines "asphyxiation" as "a state of asphyxia; suffocation," and "asphyxia" as "apparent death, or suspended animation, in living organisms, due to deficiency of oxygen and excess of carbon dioxide, specif., in the blood, as in interruption of respiration from suffocation or drowning, or from the inhalation of irrespirable gases." "Suffocation" is defined in Dorland's American Illustrated Medical Dictionary (ed. 16) as "the stoppage of respiration, or the asphyxia that results from it," while the same authority defines "asphyxia" as "suffocation; also suspended animation from suffocation or a deficiency of oxygen in the blood."

In view of these definitions, the court was convinced that a person suffers death as the result of suffocation by gas whether death was due to a deficiency of oxygen in the blood or to an interruption of the physical act of breathing that would prevent the inhalation of sufficient oxygen into the lungs. The judgment of the trial court for the plaintiff for the limited benefits provided in the policies was therefore affirmed.—*Stone v. Physicians Casualty Assn. of America (Neb.)*, 266 N. W. 605.

## Society Proceedings

### COMING MEETINGS

- American Academy of Orthopedic Surgeons, Cleveland, Jan. 11-13. Dr. Philip Lewin, 55 East Washington St., Chicago, Secretary.
- American Orthopsychiatric Association, New York, Feb. 18-20. Dr. George S. Stevenson, 50 West 50th St., New York, Secretary.
- Annual Congress on Medical Education, Medical Licensure and Hospitals, Chicago, Feb. 15-16. Dr. William D. Cutter, 535 North Dearborn St., Chicago, Secretary.
- Eastern Section, American Laryngological, Rhinological and Otolological Society, Boston, Jan. 7. Dr. D. C. Jarvis, Quarry Bank Bldg., Barrre, Vt., Chairman.
- Middle Section, American Laryngological, Rhinological and Otolological Society, Chicago, Jan. 11. Dr. Alfred Lewy, 25 East Washington St., Chicago, Chairman.
- Mid-Western Section, American Laryngological, Rhinological and Otolological Society, Chicago, Jan. 11. Dr. Frederick A. Figi, 436 Tenth Ave. S.W., Rochester, Minn., Chairman.
- Pacific Coast Surgical Association, Seattle, Wash., and Victoria, B. C., Feb. 24-27. Dr. H. Glenn Bell, University of California Hospital, San Francisco, Secretary.
- Society of Surgeons of New Jersey, Newark, Jan. 6. Dr. Walter B. Mount, 21 Plymouth St., Montclair, Secretary.
- Southern Section, American Laryngological, Rhinological and Otolological Society, Memphis, Tenn., Jan. 13. Dr. Charles D. Blassingame, Physicians and Surgeons Bldg., Memphis, Tenn., Chairman.
- Western Section, American Laryngological, Rhinological and Otolological Society, San Diego, Calif., Jan. 30-31. Dr. David R. Higley, 3245 Fourth Ave., San Diego, Calif., Chairman.

## Current Medical Literature

### AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (\*) are abstracted below.

**Virus Tumors.**—Rous deals with the difficulties that stand in the way of the supposition that the general run of malignant growths are due to viruses. 1. The cause of cancer must be present wherever man is. But wherever he goes so do certain of his parasites. May he not take viruses as well? 2. The sporadic occurrence of cancers attests the lack of infectiousness. The natural incidence of the chicken tumors yields no sign whatever that they are caused by a virus. Their occurrence is highly conditioned and some of them obviously represent a triumph over resistance offered by the host. 3. In the failure of attempts to demonstrate an extrinsic cause for the generality of malignant mammalian tumors, technical difficulties may have been mistaken for a biologic principle. 4. The appearance of malignant tumors of the same sort in identical twins or in hereditary glioma of the retina and in von Recklinghausen's disease may mean no more than that when the soil and the contributory circumstances are right a carcinogenic agent, perhaps a virus, is effective as it would not otherwise be. 5. The experimental induction of cancer at sites where it never occurs normally indicates that some decisive condition or agent is evidently present in the areas at which they arise. Andrewes has given reasons for supposing this agent to be a virus entering the organism previously and ensconced in the epithelium at the time when the carcinogenic substance is applied—an indigenous virus, as he terms it. 6. Cancer does not spring full blown from normal cells but develops as the result of gradual and often long continued changes: The changes induced by all the various carcinogenic agents may be of a sort to urge a symbiotic virus or viruses to pathogenic activity. 7. Metastases of several differing sorts, representative of more than one germ layer, are occasionally encountered in patients dying of a teratoma that becomes malignant. Many teratomas are supposedly derived from pluripotential sex cells and, if one of these became infected with a tumor-producing virus, secondary growths of diverse character would occur as a matter of course. 8. Since viruses are highly specific in their action, one causing osteochondrosarcomas of the fowl, for example, another endo-theliomas only, an entire microcosm of viruses would be needed to account for all the malignant tumors. The assumption that certain tumors may be due to viruses should be accepted only so far as to lead one to make tests with these growths.

**Clinical Observations at High Altitude.**—Talbott and Dill consider that the residence of from two to fourteen years of six healthy workmen at 17,500 feet is sufficient to call them permanent inhabitants. The unanimous admission of symptoms of acute mountain sickness in the first days after arrival at this altitude suggests that their occurrence is no indication of the ability to become acclimated to elevations as high as 17,500 feet. Colloid goiter and hyperthyroidism were not observed in any of the workmen. Other significant points in the physical examinations were normal blood pressure, a normal respiratory rate at rest, an emphysematous-like contour to the chest and clubbing of the fingers. In three subjects the pulmonic second sound was accentuated and greater than the aortic second sound. The average pulse rate for the six men at rest was 64. The absence of tachycardia at a high altitude suggests that the tachycardia of cardiac decompensation is not directly related to anoxemia. The data obtained from the examination of the arterial blood show among other changes a large increase in the oxygen capacity, cell volume and red cell count. The lowest saturation of arterial blood observed was 67.6 per cent, the highest was 84.6 per cent and the average for the six men was 75 per cent. In ten temporary residents at the same time of year at this altitude the average saturation was 76.2 per cent. The absence of any difference between the arterial saturation in the temporary and the permanent residents suggests that permanent acclimation is not associated with any significant change in this function of the blood. The average concentration of hemoglobin in cells for normal men at sea level is from 44 to 46 per cent of their volume of cells per liter. The average for the six subjects was 44. The carbon dioxide content of arterial serum varied between 30 and 40 per cent of its volume for the six men. The  $pH$  of the arterial serum reflected a mild degree of acidosis. The serum concentrations of potassium and chloride were normal or above normal and the concentrations of sodium were below normal. The concentrations of protein and calcium were within normal limits. The environment, symptomatology, physical examination and laboratory data of mountain sickness are distinct and in their totality are unlike any other disease. The syndrome represents more than the physiologic response to a high altitude. The disease is associated with prolonged anoxemia but the part that this plays in the pathogenesis is uncertain. Chronic mountain sickness is a progressive disease which manifests a remarkable recovery under increased oxygen pressure.

**Resistance and Susceptibility to Poliomyelitis and Diphtheria.**—In a series of neutralization tests with sixteen diphtheria antitoxic horse serums, Jungeblut secured complete inactivation of poliomyelitis virus of four samples and partial inactivation of one sample. There was no relationship between antitoxic potency and poliocidal power. Three monkeys that survived a full course of active immunization against diphtheria were protected against intracerebral infection with poliomyelitis virus. On reinfection, two animals developed a slight paresis, the third remaining entirely free from any symptoms of the disease. Poliocidal substances, although occasionally demonstrable in the serum of diphtheria-immune monkeys, appear with marked irregularity and show no correlation to the degree of antitoxic immunity, and their concentration at best is only very weak. The author sent 350 questionnaires in an attempt to gather further data as regards the relative frequency of diphtheria and poliomyelitis in the same child. Only 182 replies were received, with partial or complete answers. Among these were sixteen cases giving a definite history of diphtheria before the attack of poliomyelitis. This would tend to indicate a greatly increased incidence of diphtheria among the group of poliomyelitis patients (ages mostly from 1 to 10 years) when contrasted with the attack rate of diphtheria for the child population at large in New York City in the standard age group of from 1 to 9 years during the same period, which varied from 1.97 to 1.2 per thousand. Precise data as to the absence or presence of previous antidiphtheritic immunization and the clinical type of the disease were obtained from 165 returns. Among a group of seventy cases of poliomyelitis developing in children previously immunized against diphtheria, forty-five were of the paralytic type and twenty-five were listed as abortive. The other group of ninety-five cases of poliomyelitis developing in children who gave no history of previous antidiphtheritic immunization included seventy-five paralytic and twenty abortive cases. The material is meager, but it would seem that the incidence of paralysis was somewhat reduced in the diphtheria-immune children. The data are strongly suggestive of the operation of some common basic mechanism that governs susceptibility and resistance to both poliomyelitis and diphtheria.

**Effect of Hemorrhage on Emptying Time of Stomach.**—Van Liere and his associates determined the normal gastric emptying time fluoroscopically in four healthy male subjects. After one tenth of their calculated blood volume was withdrawn, the gastric emptying time was prolonged an average of 41 per cent. In no case was it less than 25 per cent. Twenty-four hours after the hemorrhage, three of the four men still

showed a delay of from 15 to 20 per cent. One subject showed no delay twenty-four hours after the blood had been withdrawn. At the end of forty-eight hours the stomach had apparently regained its normal motility in all the subjects. The observations were also made on two dogs. They too showed a distinct prolongation in gastric emptying time.

**Epilepsy.**—Paskind and Brown discuss the differences in the presence of stigmas of degeneracy (malformations about the head and face) in epileptic patients with and without deterioration. They believe that stigmas of degeneracy may be accepted as constitutional, since they are developmental anomalies which remain unchanged throughout life, except for changes implicit in growth. The material for the comparisons consisted of seventy-nine epileptic patients with deterioration from three state hospitals and thirty-nine patients with no deterioration from three outpatient clinics. In order to allow time for deterioration to occur, no patient was accepted for the group of those not showing deterioration unless he had had seizures for at least four years; many of these patients had had seizures for decades. The results of the investigation show that all stigmas, with the exception of attachment of the ear lobe, accessory anthelix, partially fused helix and anthelix, unusually prominent upper lip and abnormally high palate, were more common in the deteriorated patients. In most instances these differences were marked, certain stigmas occurring several times as frequently in the deteriorated as in the nondeteriorated patients. In other instances certain anomalies were found in the deteriorated patients that were absent in the nondeteriorated patients. Anomalies of the eye were more than twice as common in deteriorated than in nondeteriorated patients, and those of the teeth were more than three times as common. Anomalies of the skull were less than one-third as frequent in nondeteriorated patients; those of the nose were one-half as frequent. Defects in palatal structure were almost twice as common in deteriorated as in nondeteriorated subjects. Of the deteriorated patients 56.6 per cent had twelve or more stigmas; in the group of nondeteriorated patients such profuse stigmatization did not occur in a single instance. It seems reasonable to believe that there is a correlation between stigmas of degeneracy (somatic developmental anomalies) and cerebral developmental anomalies. This suggests that an essential difference between institutionalized deteriorated and extramural nondeteriorated patients with epilepsy may be the more frequent presence of cerebral developmental anomalies in the patients with deterioration.

**Klippel-Feil Syndrome.**—Avery and Rentfro report a case of the Klippel-Feil syndrome with a pathologic study of the changes in the spinal cord. Not only did abnormalities exist in the upper portion of the dorsal and in the cervical region but throughout the dorsal vertebrae there was a cleft appearance of the bodies, seemingly indicating that the two developing halves of the body did not fuse well in the midline. What might be a hemivertebral body was seen in the instance of the second dorsal vertebra. There was also evidence that fusions occurred between the vertebral bodies. The segments of the

vertebral column were fairly well represented by the number of vertebral arches. It is suggestive that there was numerical reduction not of the segments but only of the vertebral bodies. The character of the defect in the spinal cord was also in the nature of a cleft in the posterior aspect of the cervical and the upper portion of the dorsal region. At these levels complete formation of the spinal cord failed to occur, so that a central canal was not formed but was represented by a layer of ependymal cells lining the posterior margins of the cord. Even at lower levels, at which the cord had been formed completely, the central canal was of abnormal location, size and contour. Other structures also were involved in the defect, as evidenced by gliosis of the posterior columns and distinct deviations in the character of the blood vessels and the connective tissue. These changes are referable to defects occurring in the formation of the original neural tube and are, the authors believe, a true expression of dysraphia.

### Congenital Arteriovenous Anastomoses of Extremities.

—Veal and McCord present seven cases of congenital abnormal arteriovenous anastomoses of the extremities. The underlying principle, as stated by Sabin and by Woollard, is that the common capillary plexus on which both arteries and veins develop is the basis for the persistence of a direct communication between the two systems. That the condition is not often considered a diagnostic possibility is shown by the fact that, of the twenty-three cases reported by Horton from the Mayo Clinic, in only one was the condition recognized prior to the patient's admission. Undoubtedly many cases have been overlooked in all clinics, while in others the disease has been diagnosed as varicose veins or ulcers, trophic ulcers, thrombophlebitis, arthritis, elephantiasis or peripheral vascular disease and treated accordingly. The first principle of diagnosis is a careful history. All patients should be questioned closely concerning the onset of their varicosities, the location of the first noted and the possible etiologic factors involved. Cases of varicose veins which follow thrombophlebitis, infections of various sorts, surgical incisions and repeated pregnancies rarely need further consideration from this standpoint. But the group of cases in which the varicosities present early in life, without obvious cause, in which they are unilateral and in unusual locations and in which they are associated with ulceration, arthritic changes and hemihypertrophy need further consideration, though again only a small number of them will prove to be true abnormal arteriovenous communications. The cases should be studied by gross comparative examination of specimens of blood from the normal and from the affected extremity, by the oxygen saturation test and by arteriography. The oxygen saturation test reveals the exact location of the anastomosis and is of decided value in cases in which the anastomosis is not sufficiently extensive to change the character of the blood throughout the limb and in which the diagnosis may be missed because the specimen of blood is taken from an

area too remote from it to be affected by it. By means of arteriography it is now possible to locate the supposed anastomosis with absolute accuracy as well as merely to confirm its existence. Injection of the vascular system with stabilized solution of colloidal thorium dioxide demonstrates as no other method can the exact site of the abnormal communication, its size and the number and extent of the vessels involved. The arteriograms are not always easy to interpret, and abnormalities involving the small arteries and veins can be detected then only by comparison with normal standards. Through use of arteriography it is possible to determine which patients should be treated by surgical measures, which can safely be treated by the injection of sclerosing substances if the Perthes test demonstrates the adequacy of the deep circulation and which must be left untreated unless and until amputation proves necessary.

**Air Conditioned Rooms in Treatment of Asthma.**—The results of Trasoff and Blumstein with forty asthmatic patients confirm those of Gay, who was able to obtain favorable results in his asthmatic patients within one hour after their admission to an air conditioned room, and that of Nelson, Rappoport and Walker, who report 50 per cent improvement in their asthmatic patients within three hours or less. Only certain extrinsic forms of asthma are likely to benefit from this method of treatment. One should not expect to obtain relief in such an atmosphere when sensitivity exists to the animal danders, which are contained in that room, such as feathers. Intrinsic factors are not controlled or removed. As in the case of Gay, patients suffering from bacterial allergy cannot expect any benefit in such rooms. This explains the failure of treatment in the perennial as well as mixed asthmatic patients in air conditioned atmospheres. The air conditioned room has some diagnostic value. Failure to obtain immediate relief in such an atmosphere would justify the exclusion of pollen as a factor.

**Fever Accompanying Pernicious Anemia.**—In a series of 206 cases of pernicious anemia in which remissions were induced by liver therapy, Fowler observed fever ranging from 102.4 to 106 F. coincident with the reticulocyte crisis in eight

cases. In each of these cases a concentrated form of liver extract was administered, to one patient intramuscularly, to the others orally. Every conceivable extraneous cause for fever was excluded. The temperature rose rather suddenly, returning to normal more gradually over a period of from twenty-four to forty-eight hours. In two cases in which reticulocyte counts were being done daily, the highest temperature coincided exactly with the highest reticulocyte count and in three it occurred during the period of decline. In the three cases in which reticulocyte counts were not made, the fever appeared during the time when the crisis was to be expected. In several of the cases the fever was accompanied by a slight chill; in the others there were no associated symptoms of any kind. None of the patients had a leukocytosis. There was no apparent relationship between the occurrence of fever and the pretherapeutic erythrocyte level. The continuous low grade fever characteristic of pernicious anemia during relapse, manifested by many of the 206 patients, disappeared in most cases after the reticulocyte crisis. The fever observed was not referable to the reticulocytosis alone, and the authors are unable to give a satisfactory explanation of its mechanism.

**Storage of Vitamin C by Normal Adults.**—O'Hara and Hauck planned and administered to four normal women a basal diet adequate in other respects but containing only 5 mg. of vitamin C. They found that the amount of vitamin C necessary to restore the tissues to saturation after a month on this diet ranged from 2,200 to 2,800 mg. when administered in daily doses of 200 mg. The difference between intake and excretion up to the point of saturation following prolonged deprivation of vitamin C may afford some indication of the maximal vitamin C reserve. On this basis, tissue reserves at saturation appear to be of the order of from 2,500 to 3,000 mg. In these experiments, capillary resistance did not give an adequate indication of the state of nutrition with respect to vitamin C.

**Narcosis Therapy in Psychoses.**—During the last six months Alexander employed deep narcosis therapy in five cases, in one of which discontinuance of the therapy was forced on the fourth day, because of potentially dangerous physical complications. Of the four completed cases, two patients were well enough to leave the hospital approximately one week following narcosis therapy and have remained entirely well for periods of four and six months respectively. Both of these patients presented variable degrees of excitement, bizarre behavior, delusions and probably hallucinosis and were classified as schizophrenic reaction types. The patient presenting a deep stupor reaction and persistent preoccupation, with suicidal trends, responded with definite improvement for a period of two weeks, followed by gradual relapse, although not to the same low level as existed prior to narcosis treatment. The remaining patient, who presented an acute excitement in a predominantly manic-depressive, manic picture, failed to show any improvement following narcosis therapy. Sodium amylal was used exclusively as the narcotizing agent. The question as to the specific action of barbituric acid derivatives, as opposed to a general effect of a prolonged period of narcosis, however produced, must remain unanswered until prolonged narcosis is obtained by other drugs. Whatever the fundamental mechanisms underlying narcosis therapy may be, and despite our lack of accurate knowledge of them today, a sufficiently close temporal approximation is noted between treatment and response to warrant the assumption of a causal relationship, as opposed to merely coincidental improvement, or improvement associated with the normal course of recovery from the illness, and to sustain the feeling that, in the treatment of selected psychotic states, prolonged narcosis therapy has a definite value.

**Indications for Open Operation in Fractures.**—Schoolfield gives the following indications for open operation: fractures that cannot otherwise be replaced and maintained or cases in which too much loss of time would be occasioned by conservative methods, interposition of soft parts between fragments, or small isolated fragments that have not united, in all likelihood will not unite and are not essential to good function, nonunion and malunion. Of the fractures requiring open reduction, transverse fracture of the patella is a preeminent example. Wide separation of the fragments usually results

from the strong pull of the quadriceps group. Open reduction should be the rule in such circumstances. Fractures of the olecranon will often show more rapid and definite results with open fixation, though much will depend on the amount of separation of the fragments. Fractures about the distal end of the humerus will often require open reduction and fixation. The humerus, femur, radius, ulna and even the tibia are often the seat of fractures that do not lend themselves to sustained reduction. This may be due to the obliquity, the presence of unmanageable, sharp-pointed spicules or other mechanical difficulty, aided and abetted by marked muscular spasm. Open reductions are especially demanded in fractures neglected for days or weeks. Open reduction and fixation should be considered in the transverse fracture of the posterior part of the os calcis with its natural tendency to upward displacement because of the pull of the calf muscles.

**Toxemia of Pregnancy.**—Goodall considers that there is but one toxemia of pregnancy in the third trimester but that it has a very protean symptomatology. The reason for this lies in the idiosyncrasies of the patients and in the susceptibilities and reserves of systems and of individual organs to a common toxicity which bathes all the tissues generally and commonly. Susceptibility to eclampsia varies in different patients. It is important to recognize this factor, as it frequently determines the course of the disease. In the child-mothers the susceptibility to eclampsia is high, owing to instability of their nervous systems. Many women, though chronologically mature, are infantile in nerve development and instability and as such are as susceptible as children to the convulsive expression of toxemia, when from their years one might expect a milder form of reaction. The blood pressure in the early months of pregnancy ranges between 30 and 60 diastolic and between 60 and 90 systolic. It slowly rises in the third trimester under normal conditions but should not exceed from 70/100 to 80/110. In abnormal states, blood pressure begins to rise and may reach very high registration throughout the later months. In the third trimester, high maternal blood pressure leads to grave placental disease and coincidentally grave fetal circulatory disturbances. High blood pressures are commonly associated with progressive placental edema, deposition and sclerosis. Toxemia does not affect the placenta in this manner. Toxemia produces placental hemorrhages and placental retroplacental and intraplacental hemorrhages are found principally in true toxic cases and usually in the low grade types of toxemia, cumulative and of long standing, but rarely with a blood pressure greater than 125 systolic. Placental

and its final expression, massive death of the placenta, is found in the acute true toxemias. The vast majority of cases of clinical toxemia have no symptoms, and the only signs are a progressive pallor and an intractably rising blood pressure. These are not cases of uncomplicated toxemia. They are toxic cases only possibly in a secondary way. But primarily the blood pressure arises out of dyscrasias other than those due to pregnancy. They constitute the great majority of the patients who have persistence of high blood pressure after delivery and eventuate after some years into chronic cardiovascular-renal cases. In such cases pregnancy is merely an incidental association, not without its influence on the primary disease and not always a baneful associate.

**Surgical Treatment of Carcinoma of Penis.**—Nesbit and Keitzer agree with Dean and Campbell that a lesion involving less than the distal half of the penis should have simple amputation from 1.5 to 2 cm. proximal to the involved portion. In cases in which there are regional metastases, gland dissection should be done at a later date if deemed advisable. The authors' technic of local amputation is as follows: After sterile preparation of the patient, the glans, with the lesion, is wrapped in sterile gauze to avoid contamination of the wound. A circular skin incision is made about the penis, from 1.5 to 2 cm. proximal to the involvement. The skin is bluntly dissected toward the base for a short distance and the dorsal vessels are ligated. The ventral aspect of the organ is now brought into view and the corpus spongiosum is incised at the level of the original skin incision. A number 20 F. catheter is inserted into the urethra to be used as a guide during the dissection of the corpus spongiosum from the corpora cavernosa. If the line of cleavage is found, the procedure is relatively easy; otherwise one must avoid injury to the spongy body and urethra by sharp dissection within the adjoining capsules of the corpora cavernosa. The corpora cavernosa are transected 1.5 cm. above the level of the corpus spongiosum. The cavernous arteries are ligated. Two heavy chromic mattress sutures are placed horizontally through the entire thickness of the corpora cavernosa. These sutures shape the distal end of the stump. Four vertical sutures through the corpora cavernosa capsule bring the stump to a conical shape. A suture tacks the corpus spongiosum over the rounded end, bringing the urethra out the midpoint with 1 to 1.5 cm. projecting beyond the end of the stump. The skin is trimmed to fit the stump and closed on a horizontal line with interrupted silk sutures. The importance of allowing the corpus spongiosum to project beyond the stump cannot be overemphasized. The retraction that always occurs provides a normally functioning meatus, which projects a millimeter or two and allows the free passage of a normal urinary stream. Failure to allow for this retraction results in either stricture or retraction of the meatus, or both. Petrolatum gauze dressings are applied and changed daily. The catheter is left in until the skin sutures are removed. The end result is a well shaped and satisfactory urinary and sexual organ.

**Treatment of Trichomonas in Male.**—During the last seven years, thirty cases of male Trichomonas infections have been observed in clinical and private practice by Cornell and Riba. It is their impression that the Trichomonas infection in the male is acquired solely through sexual contact. There may be no symptoms. Usually symptoms of chronic prostatitis are present. A urethral discharge is present when the urethra is involved. Examination of fresh urethral and prostatic secretions or urinary sediment with the microscope will reveal the motile organisms. In general, the same principles of treatment have been used as in other nonspecific infections of the lower part of the urinary tract in males. Prostatic massages and urethral and deep instillations have caused a disappearance of Trichomonas in all cases that were treated adequately and followed up. Five cases of Trichomonas prostatovesiculitis were complicated with multiple strictures of the anterior urethra. The damaged urethra may be a factor in paving the way for Trichomonas infections. Three of the wives who have been examined harbored Trichomonas in the vagina. When urethral strictures are found, they should be eradicated if possible. Weak acriflavine base solution (1:2,000) has been the most useful drug in clearing up the urethral infections.

English Dysenteric Infections. A. F. Hurst.—p. 598.

**Errors in Average English Dietary Exposed by Pregnancy.**—Theobald advances the hypothesis that all the toxemias of pregnancy, including the pyelitis of pregnancy and puerperal insanity, are caused by deficiencies in the diet. The earliest manifestation of the toxemias of pregnancy is the onset of one or more of the following symptoms: insomnia, headaches, cramps and vomiting. These symptoms, in the absence of some definite cause, arise as the result of disturbance of the calcium metabolism. The dietetic deficiency hypothesis differs fundamentally from all the other hypotheses that have been advanced to explain the etiology of the toxemias of pregnancy. Not only does it correlate all the toxemias of pregnancy but it implies that there is no essential etiologic difference between ordinary morning sickness and the decay of teeth associated with pregnancy on the one hand and eclampsia on the other. All recent surveys of the dietaries of the people of England have shown that the average individual in the islands is inadequately fed. Secondary anemia is much too prevalent among the women in this country. The author has suggested that every school throughout the country should instruct girls to take iron for one month in the year. The other substances of which pregnancy teaches that there is all too frequently an inadequate intake are vitamins A, B and D and iodine.

Acholuric Jaundice in the Adult. M. Kremer and W. H. Mason.—p. 849.

**Treatment of Asthmatic Attacks.**—Nielsen treated more than 400 attacks of asthma in forty patients with inhalation of a 10 per cent solution of epinephrine, nebulized in the triplex or asthminhal spray. The dose may be expressed in milligrams, each compression of the ball of the triplex spray (side tube) nebulizing an amount of the solution corresponding to one-twelfth mg. of epinephrine, each compression of the asthminhal spray corresponding to one-eighteenth mg. The dose has varied between one-sixth and 1 mg., most often being from 0.5 to 0.75 mg. In all cases the treatment was very successful. The effect appears almost immediately. In slight attacks the respiration is eased after a few inhalations of the solution, and half a minute after the end of the inhalation the respiration is no longer sibilant and the rhonchi have disappeared. In a case of status asthmaticus, in which subcutaneous injection of 1 mg. of epinephrine had been without effect, the condition improved considerably on inhalation. It is difficult to determine the duration of the effect obtained. In a few cases, when the patients were in status asthmaticus, the effect seems to have lasted a fairly short time, though seldom less than an hour; in one case, however, it was only ten minutes.

No change in sensitivity toward epinephrine was observed. The patients have not complained of palpitations or other subjective symptoms. One patient inhaled 1 mg. of epinephrine twelve times at intervals of an hour without any inconvenience. The favorable result is considered to be due to a local effect of epinephrine.

**Thick Blood Drop Method of Diagnosis in Leprosy.**—In performing Clouston's procedure the first drop of blood taken from an apparently well finger or thumb is wiped away and then another drop is taken and a thick drop preparation is made. This is then dried in air, under glass covers, dehemoglobinized in distilled water and again dried as before. The film is then stained by the Ziehl-Neelsen method, 5 per cent sulfuric acid being used for decolorization. Counterstaining is carried out with aqueous methylthionine chloride for three minutes. To test the efficacy of the method employed, eighteen nodular cases were investigated; acid-fast bacilli were found in skin sections and nasal smears in all. Fourteen cases showed acid-fast bacilli in the thick blood drop preparation. In the majority of the preparations acid-fast bacilli were abundant, being present both singly and in clumps and many being intracellular. In addition to the nodular cases, the blood of thirty-six patients in segregation with milder cutaneous leprosy was examined. Acid-fast bacilli were found after prolonged search in only two cases. Blood films from twenty-one persons attending the outpatient clinic were also examined. No evidence of Microbacterium leprae was found in any of these films. The patients from whom these films were taken had all suffered from neural leprosy, their infections were all clinically inactive and the examination of skin sections and nasal smears within the last two years has given negative results, eighteen having given negative results within the last nine months. Ten suspected patients were also examined with negative results. These were patients having a small area of hypopigmentation, not necessarily, though usually, associated with anesthesia or analgesia and with no acid-fast bacilli in skin section or nasal smear. Negative results were obtained with eight children whose ages ranged from 6 to 10 years, born in the leper station of leper mothers. The results of this investigation support the conclusions reached by Lowe in India. The technic is not suitable for early or latent cases of leprosy.

- \*Cholesterol and Methylated Antigen Associated in Treatment of Tuberculosis. F. Barbary.—p. 242.

**Bactericidal Power of Serum in Tuberculosis.**—Courmont and Gardère report observations on the prognostic value of the bactericidal action of serum in pulmonary tuberculosis. Previously they described how in vitro tests of the bactericidal power of serum to homogeneous liquid cultures of the tubercle bacilli could be performed. Culture growth could be stimulated or inhibited by the addition of the serum removed from certain tuberculous patients. The method in brief involves the use of four tubes of culture medium with definitely measured proportions of bacilli and serum. The forty cases studied in this report were taken from persons with active tuberculous lesions. The blood was drawn during the first days of hospitalization and before any treatment had been instituted. Eleven of these patients had a weak bactericidal power and five of these died. The other twenty-nine patients showed a strong bactericidal power of the serum and only four died. Thus, among the group of patients showing the weak bactericidal power of the serum, 45 per cent died, while only 13 per cent of those with a strong bactericidal serum died. They concluded from these and previously published results that investigation of the bactericidal power of the serum can be of some prognostic value in pulmonary tuberculosis. From the standpoint of general pathology these facts are important: it seems logical to believe that increase in the bactericidal power of the blood of certain animals almost entirely refractory to tuberculosis and the elevation of bactericidal power of the blood of tuberculous persons are excellent signs of general resistance.

**Cholesterol and Methylated Antigen in Treatment of Tuberculosis.**—Barbary adopted a preparation consisting of 0.05 cc. of benzyl cinnamate, 0.1 cc. of pure cholesterol, 0.125 cc. of camphor and 5 cc. of pure olive oil washed with alcohol in the treatment of tuberculosis. One ampule containing 5 Gm. of this solution and 0.5 or 1 Gm. of the dilute methylated antigen of the Pasteur Institute and, finally, another ampule of the prepared solution were aspirated into a 10 cc. syringe. The mixture was then injected subcutaneously but extremely slowly. For the first two weeks the injections were made twice a week. On each intervening day two ampules of the cholesterol solution without the antigen were injected. Following this course of treatment there was a week of rest. For the succeeding two weeks the same technic was repeated but the amount of antigen doubled. The procedure was continued as long as necessary. There were no reactions, no shock and no interruption of daily occupation from this method of treatment. It is applicable in different forms of tuberculosis, including the pulmonary, osseous, cutaneous and ganglionic, and is effective in adults as well as children. The results were slow with some and fast with others but were evidenced by an arrested evolution of the process, drop in temperature, increase in weight and a more or less active regression of the lesions.

**Presse Médicale, Paris**

44: 1681-1704 (Oct. 28) 1936

- Late Results of Albee's Operation for Pott's Disease of Adult. G. Leclerc.—p. 1684.

**Hemostatic Effects of Octylic Alcohol.**—Clerc and his colleagues state that previous work has demonstrated that bodies which lower superficial tension exert a coagulating action on the blood. This action can be demonstrated by simple mixtures in vitro, but it is even more marked following intravenous injection in the dog. They report ten cases, in all of which hemorrhagic states existed from various causes, treated in the attempt to increase the coagulability of the blood. The preparation used consisted of a pure octylic alcohol in 10 per cent ethyl alcohol, the eventual titer being about 1:1,000. Fifteen cubic centi-

meters of this solution was injected slowly into the vein. The coagulation time was taken from the vein of the opposite arm immediately before and fifteen minutes after the injection. Bleeding time was also determined by the classic method of Dukes. The most important result of these experiments was the definite harmlessness of the method. The coagulation time was found shortened in eight of nine patients. This was effected with great rapidity. The degree, however, varied from case to case. The duration varied widely but was observed to last from about seven days to eight weeks. The bleeding time seemed to be little modified. The clinical results were favorably influenced and there was a tendency for hemorrhages to disappear. The mode of action remains obscure. Because of the innocuousness of the procedure it can be tried without risk in any case of hemorrhagic state. While further investigation is necessary, these preliminary results are encouraging.

- \*Alterations of Structures at Base of Cranium in Lipoid Nephrosis. G. Barbaro-Forleo.—p. 696.
- Behavior of Glycemia in Acute Inflammation of Lung. A. Bologna and G. C. Sironi.—p. 705.

**Changes in Structures at Base of Cranium in Lipoid Nephrosis.**—Barbaro-Forleo reports two cases of lipoid nephrosis. The roentgen examination of the structures at the base of the cranium showed the presence of sphenoid sinusitis, perisinusitis of the nearby sinuses and anatomic changes of the structures of the thalamo-encephalohypophyseal region. The author believes that lipoid nephrosis originates in dysfunctional disturbances of the hypophysis and the thalamo-encephalon. He advises x-ray examination of the base of the cranium in other cases of lipoid nephrosis and, if possible, anatomopathologic studies of the hypophysis and diencephalon in necropsies made on cadavers of persons who suffered from lipoid nephrosis.

- \*D'Amato Sign for Diagnosis of Pleural Effusion. A. Sacchetti.—p. 1476.

**Diagnosis of Pleural Effusion.**—The D'Amato sign for diagnosis of pleural effusion consists in the change of dullness from the vertebral column to the cardiac area for displacement of pleural fluid from the posterior to the anterior costomediastinal sinus during postural changes of the patient. The sign was described by the author in the *Riforma medica* 51:1503 (Oct. 5) 1935 and abstracted in *THE JOURNAL* Dec. 28, 1935, page 2190. Sacchetti investigated the sign in a great number of cases. His results confirm those of D'Amato with respect to the value of the sign in diagnosis of pleural effusion. The author advises resorting to the sign, which he considers easy to determine and as valuable as Maragliano and Grocco's signs, for the diagnosis of pleural effusion and for the differential diagnosis of several diseases of the respiratory tract.

- Prevention of Tuberculosis. J. R. Da C. Doria.—p. 1000.

**Alkali Reserve in Tuberculosis.**—Baer Bahia says that acidosis is one of the most frequent complications of tuberculosis. Whether acidosis precedes the development of tuberculosis or is caused by it is not known. In tuberculous acidosis a vicious circle is established. Acidosis retards the processes of organic combustions and this retardation increases the acidity of the body fluids. Administration of tuberculin induces modifications in the acid base equilibrium. Patients with a low alkali reserve show an intolerance to tuberculin, which is manifested by tachycardia and loss of weight. Patients with a

normal or slightly increased alkali reserve show a relative bradycardia and increase in weight after the administration of tuberculin. Gold salts administered to tuberculous patients induce a decrease in the alkali reserve which oscillates between 10 and 20 per cent. The decrease of the alkali reserve in these cases is independent of the dose of gold salts injected provided it does not surpass from 0.25 to 0.1 Gm. of the salt. A decrease in alkali reserve is produced immediately after the injection and lasts about three hours and a half. In cases of intolerance to gold salts the use of sodium bicarbonate or citrate controls intolerance. The study of the physiology of the acid base equilibrium in tuberculosis shows the importance of metabolic disturbances in the beginning and development of tuberculosis. The latter is an infection, but its development depends on special dysergic conditions of the patient.

\*Does Function of Diaphragm Return in Phrenicectomized Patients? R. M. Boza Mesa.—p. 1103.

Infantile Hysteria Cured by Psychoanalysis. B. Cardelle y Penichet and L. Muñiz Angulo.—p. 1125.

**The Diaphragm in Phrenicectomized Patients.**—Boza Mesa states as a fact that the diaphragm resumes its function after phrenicectomy. He followed the evolution of paralysis in a group of eight patients and found that in all cases the collapse of the lung was successfully obtained and the mobility and functions of the diaphragm were reestablished within one and five years after phrenicectomy. The several hypotheses given in the literature as an explanation for the resumption of diaphragmatic functions are supplementary innervation by the phrenic nerve of the opposite side to that on which phrenicectomy was done, and innervation from the intercostal, subclavian or accessory phrenic nerves or else by sympathetic fibrils. The author's report confirms the reports in the literature on the reestablishment of diaphragmatic function after phrenicectomy and the time in which the function is resumed. The mechanism by which mobility and function of the diaphragm are reestablished depends on certain factors not yet determined.

**Adiposogenital Dystrophy from Late Syphilis.**—In the case reported by Galand a man, aged 69, acquired syphilis at 23 and was insufficiently treated. Some time later he married and had two children. At the age of 38 he suffered from a semigeneralized alopecia, which left only a small amount of hair on his head. This was followed soon by the establishment of excessive thirst, polyuria, feminine obesity, diabetes insipidus and a typical Fröhlich syndrome. The condition lasted ten years, at the end of which time he was given antisyphilitic treatment, which controlled obesity and diabetes and started regrowth of the hair. The treatment, however, had no effect on the sexual disturbance. A diagnosis of adiposogenital dystrophy from late syphilis was made. The blood changes (oligocythemia, oligochromemia and mononucleosis), the presence of metabolic disturbances and the conservation of a clear mind, which are characteristic properties of adiposogenital dystrophy, were present in the patient's case. The syphilitic etiology is undoubted. Roentgen studies of the skull and of the sella turcica showed normal structures, but the functions of the hypophysis could not be evaluated. The author believes that the adiposogenital dystrophy developed from functional disturbances of the hypophysis by a syphilitic gumma located in the hypophyseal region or by a syphilitic meningo-encephalitic process. His opinion is based on the previous existence of obesity and diabetes (two conditions that originate in functional hypophyseal disturbances), the previous existence of thirst and

polyuria (two conditions that originate in anatomic changes of the hypothalamus) and the satisfactory results of anti-syphilitic treatment in controlling these disturbances.

**Carcinoma on Basis of Endometriosis.**—Vogt, after reviewing a case that was described by Hanser, reports a case of his own. The patient, a woman now 53 years of age, underwent roentgen castration at the age of 35 on account of severe hemorrhages. There were recurrences of the hemorrhages, which were counteracted by repeated irradiations. In August 1935 the patient was again hospitalized on account of severe hemorrhages and this time the uterus was removed by an abdominal radical operation. The recovery was uneventful, but after ten months the woman complained of a downward pressure, backache and a peculiar sensation in the rectum. The examination revealed nodular thickening of the posterior vaginal wall below the scar and a tough, irregular infiltration in the entire rectovaginal septum. The histologic examination of a nodule of the posterior vaginal wall disclosed a carcinoma on the basis of a benign endometriosis.

Bactericidal Action of Blood in Puerperal Fever and Cervical Carcinoma. F. Daels.—p. 217.

**Modification of Pregnancy Reaction According to Visscher and Bowman.**—Friedrich directs attention to the chemical pregnancy reaction of Visscher and Bowman (*Deutsche med. Wchschr.* 60:1837 [Nov. 30] 1934; abstr. *THE JOURNAL*, Feb. 2, 1935, p. 431). Numerous experiments and modifications convinced him that the outcome of the reaction is chiefly determined by the hydrochloric acid. Methyl cyanide and hydrogen dioxide seem to be least involved in the reaction, and phenylhydrazine hydrochloride gives the fluid the basic yellow color. If these three reagents are omitted, the color changes only from yellowish brown to brown. However, if these three reagents are used and only hydrochloric acid is omitted, there is no reaction whatever. To prove that the gonad-stimulating factor is the only hormone which, when treated with hydrochloric acid, produces a color reaction, the author tested a number of other hormone preparations. He found that, aside from slight turbidities produced by thyroxine and insulin, the gonad-stimulating factor remains the only hormone which, when heated with hydrochloric acid, gives a strong color reaction with a rather coarse precipitate. The same 312 urine specimens, which he examined according to the technic of Visscher and Bowman, he examined also according to two methods devised by himself. In the first he added to 1 cc. of urine, the specific gravity of which had been brought to 1.015, 3 drops of a 25 per cent solution of hydrochloric acid and heated this mixture for twenty-five minutes in a boiling water bath. A clear, permeable light brown fluid without a precipitate indicates a negative reaction, but the test is positive if the urine is reddish brown or a dark brown and if a precipitate makes it turbid. In the second method 5 drops of a 25 per cent solution of hydrochloric acid are added to 1 cc. of urine (specific gravity of 1.015). Then the mixture is heated to the boiling point for exactly two minutes over the Bunsen burner. A light brown indicates a negative reaction; a reddish brown or dark brown a positive reaction. A precipitate is usually absent with this technic. Only five contradictory results were obtained in the 312 specimens of urine (tested with the Visscher-Bowman and the author's technics). The hydrochloric acid method gave the correct results in these five cases.

**Injuries of Cerebral Vessels.**—Löhr cites cases treated at the surgical clinic of the State Hospital of Magdeburg-Alstadt in which demonstration and localization of thrombosis or injury to one of the larger cerebral vessels was made possible by arteriography. The author has in mind cases of severe injury to brain tissue presenting complicated neurologic symptoms and an indefinite history. It is here that arteriography is capable of rendering service in establishing a diagnosis and permitting more active treatment. This is particularly true of hemorrhages from the epidural or subdural vessels, since it is this type of case that constitutes the most frequent indication for surgical intervention in order to relieve the classic symptoms of increased intracranial pressure. Experience with surgery of brain tumors as well as that with hemorrhagic pachymeningitis demonstrates that, besides the purely mechanical effect, bleeding is capable of producing a toxic effect as well. The author likewise calls attention to the fact that the conservative method of lumbar puncture is not always a safe procedure in the severe cases complicated by swelling of the brain. The surgeon's problem is to be able to select from the cases of brain injury those due to bleeding and, when possible, to aid them by the removal of blood clots or by arresting the bleeding. Arteriography constitutes the most reliable method for localization of the bleeding. The method is indicated in cases of skull and brain injury in which the history and the neurologic examination fail to establish an accurate diagnosis of epidural or subdural hemorrhage.

\*Value of Microscopic Examination of Liver in Diagnosis of Death by Drowning. B. Popielski.—p. 856.

**Diagnosis of Death by Drowning.**—Popielski says that it is often impossible to make a diagnosis in cases of drowning. He reviews the literature and the minutes of postmortem examinations in cases of death by drowning and finds that the supposed signs, (1) excess of venous blood supply in the liver, (2) weight of the liver and (3) the dark red color, are the same symptoms that appear in cases of asphyxiation. He experimented on thirty-six animals and concluded that microscopic examination of the liver is not dependable and therefore impractical. He summarizes his views as follows: A superfluity of venous blood in the liver has a distinct value. It always appears in cases of death by drowning and so aids in the diagnosis. This change may be verified in histologic specimens and, when other anatomic symptoms are lacking, points to death by drowning. But it is also found in asphyxiation.

\*Insulin Therapy in Pneumonia of the Aged. S. N. Sinelnikov.—p. 603.

**Insulin Therapy in Pneumonia of the Aged.**—Sinelnikov regards pneumonia as a state of nondiabetic pathologic acidosis running a course characterized by a pronounced anoxemia with a considerable increase in the blood sugar, increased breaking

down of albumin and fat, and marked lowering of the chloride metabolism. Achard was the first to refer to insulin as an alkalizing agent, and Kogan-Yasnyy was the first to apply it in the treatment of pneumonia. The blood sugar of the pneumonia patients was found to vary between 0.120 and 0.160 at the peak of the temperature curve. With the fall of the temperature the blood sugar content was from 0.09 to 0.08 per cent. The chlorides at the height of the disease varied between 0.58 and 0.6, during the crisis from 0.93 to 6.8, and several days after the crisis from 8.8 to 12. Insulin was administered twice daily in doses of from 0.5 to 1.5 Gm. The author reports 122 cases of croupous and of bronchial pneumonia treated by this plan without a fatality. In a specially selected group of eighteen elderly patients there was not a single fatal issue. The author reports four cases in which the insulin therapy did not prevent death. On necropsy these were shown to have been complicated respectively by carcinoma, active tuberculosis, infarct of the left lung and a ruptured aortic aneurysm.

**Disturbances in Autonomic Innervation.**—Van Valkenburg describes three cases of neurovegetative disturbances of traumatic origin. In the first case a disturbance in the sympathetic innervation of the hands and the forearms developed in a man who, as the result of a fall, held himself with his hands in order to keep from drowning until he was rescued. Following this, pain and stiffness developed in his hands and he was unable to work. An examination four months later revealed changes in the hands and lower part of the arms resembling those of acromegaly (skin cold, pasty and with red and blue spots; nails dry and brittle). Some of the fingers were bent and could not be actively stretched out; attempted passive stretching caused severe pain. The sensitivity was not impaired and the electrical irritability was likewise normal. Roentgenoscopy revealed atrophy of the hands and lower part of the arms. The condition improved in the course of time. The author is convinced that the disorders were caused by a local impairment of the sympathetic innervation, which in turn resulted from the blunt force exerted on the hands in the course of the fall. The second case concerns a man in whom trophic disturbances developed in the region of the peroneal nerve following a fracture of the tibia. In the third patient the disturbances in the sympathetic innervation developed as the result of a stroke of lightning.

\*Autocerebrospinal Fluid Therapy of Epidemic Cerebrospinal Meningitis of Children. J. S. Weiner and S. F. Bakkal.—p. 214.

**Pancreatic Secretion in Man.**—Ågren and Lagerlöf state that, although Bayliss and Starling performed their classic secretin experiments in 1902, there are still authors who express doubts as to the existence of a secretin stimulation as an integral part of normal digestion. On the basis of their experiments the authors state that it is possible to give the following picture of the effect of secretin stimulation on the digestive mechanism in man: After the intravenous injection of secretin a lively discharge of pancreatic juice sets in, usually before a minute has elapsed. The volume of secretion reaches its maximum within twenty minutes, usually within ten minutes,

the peak being followed by a rather slow decline. Parallel with the volume there is, as a most conspicuous feature, a rapid rise in the concentration of bicarbonate. The concentration first lags a little behind the volume and, after the maximal concentration has been reached, declines somewhat slower than the volume. The authors consider the dosage of secretin used in their experiments a submaximal dose. With this dose the maximal bicarbonate concentration is closely milliequivalent to the blood plasma and the gastric juice. The discharge of the pancreatic enzymes follows a somewhat different course. There is during the first ten minutes a great amount of enzymes (trypsin and diastase) excreted in the first abundant secretion of juice, an amount no doubt representing material stored in the gland before the hormone stimulation. After this sudden peak a secretion of presumably new-formed enzyme becomes apparent, about the time the bicarbonate concentration reaches its maximum. This enzyme production continues at a rather constant level for a considerable time, at a higher rate than before the secretin stimulation. As the volume of the juice diminishes the enzyme concentration increases. In normal persons after the secretin injection, bile does not appear in the duodenal content or in occasional traces only. In persons who have had their gallbladder removed but who otherwise are normal, the situation is different. Here every sample after the secretin injection is more or less heavily stained with bile. Secretin thus stimulates the flow of bile in man, a flow which in unimpaired normal persons on the whole is taken up into the gallbladder just as it is in animals. The variations in secretin response in the different individuals of the series might be considered within moderate limits, the agreement between repeated tests on the same person being close.

**Autocerebrospinal Fluid Therapy of Epidemic Meningitis in Children.**—Weiner and Bakkal during 1933, 1934 and 1935 treated fifty patients suffering from cerebrospinal meningitis. Seven were treated with a polyvalent meningococcus serum, nineteen by lumbar punctures and twenty-four by subcutaneous injection of the patients' own cerebrospinal fluid. The authors were impressed with the unsatisfactory results of the polyvalent vaccine therapy. The results were poorest with the method of lumbar puncture. Of the nineteen patients so treated, fifteen died. Of the twenty-four patients treated by hypodermic administration of the patients' own cerebrospinal fluid, nineteen recovered and five died. Despite the small number so treated, the authors regard this simple method of treatment as more promising than any heretofore attempted.

Blood Groups and Gonoreaction. T. Packalén.—p. 808.

**Intravenous Anesthesia with *n*-Methyl-Cyclo-Hexenyl-Methyl Barbituric Acid.**—On the basis of 529 cases of anesthesia with the sodium salt of *n*-methyl-cyclo-hexenyl-methyl barbituric acid from 1933 to 1936, Blomquist states that the anesthesia occurs quickly and without disagreeable sensations; there is no excitation, but more or less muscular tension not infrequently occurs, perhaps with trembling of the body for several minutes. The awakening is usually quick and pleasant. It can be given without preparation, but a preanesthetic may advantageously be used, especially in young persons. It is suitable for all operations of short duration in which there is no danger of aspiration and as the introductory anesthesia in long continued interventions, particularly where there is fear of narcosis and in psychic disturbance, and is an excellent means for weak old persons. The dosage should receive especial attention; biologic dosage is recommended. The author advises against the use of this anesthetic in cases in which there are disorders of the liver and kidneys and in greatly dehydrated persons and says that the dosage must be given with greatest care in cases of toxic injury and fever. Postnarcotic unrest is an occasional drawback, and now and then a person resistant to the agent is encountered.

**Adsorption Ability of Plasma Proteins.**—Ehrström says that in cachexia due to tumor, as in nephroses in the sense of nephropathies with pronounced albuminuria, the adsorption ability of the plasma proteins is lowered and likewise does not depend on a hypoproteinemia or a hypo-albuminemia. A probable explanation of the phenomenon is to be sought in the disturbed synthesis of the plasma proteins. In nephrosis the loss of albumin through the kidneys leads to a primary reduction in the blood albumin, which is eventually compensated by an increased synthesis of plasma proteins. In cachexia from tumor the hypoproteinemia occurs because of an increased breaking down or defective synthesis. In both cases the hypothesis is that the disturbed synthesis of the plasma proteins results in the formation of plasma proteins not of equal rank with the proteins in the normal system but having a defective adsorption ability.

Two Rare Lesions of Divers. N. I. Nissen.—p. 950.

**Hyperglobinemia.**—Bing and his co-workers have previously reported two cases characterized by marked hyperglobinemia, with resulting high blood sedimentation reaction and positive formol reaction, and extensive changes in the central nervous system, especially in the cauda equina, spinal roots and medulla, together with changes in the spinal fluid. In the case now reported, a woman aged 57, with like changes in blood and spinal fluid, there were both in the central nervous system and outside it in the various organs localized inflammatory changes with numerous lymphocytes, plasma cells and cells belonging to the reticulo-endothelial system; in the bone marrow, signs of lively cell proliferation appeared but no signs of myeloma were found. Similar changes in the blood were seen in two microscopically verified cases of myelomatosis, but in the case in which the spinal fluid was examined it was normal, and in the other in which the central nervous system was examined, no changes were found which agreed with those in the three cases of hyperglobinemia with disturbance of the central nervous system described.

\*Osteomalacia of Spinal Column. E. Meulengracht and A. R. Meyer.—p. 961.

\*Xanthomatosis Universalis Given Roentgen Treatment: Case. P. A. Blinkenberg.—p. 968.

Fourth International Congress for Experimental Cell Research in Copenhagen, August 10 to 15, 1936. H. Okkels.—p. 972.

**Osteomalacia of Spinal Column.**—Meulengracht and Meyer state that in four patients, who subsisted for a long time on a one-sided diet, a disorder of the spinal column developed with osteoporosis, hour-glass deformity and breaking down of vertebrae, changes similar to those in the so-called nonpuerperal forms of osteomalacia. The factors that lead to the development of osteomalacia are assumed to have been active in these instances. Depending on the kind and degree of the causative nutritional deficiency, the changes in the spinal column may appear alone or in combination with other deficiency symptoms. A case of combination with scurvy is reported.

**Roentgen Treatment of Xanthomatosis Universalis.**—Blinkenberg says that in his case of universal xanthomatosis in a girl, aged 2, clinical recovery after roentgen treatment over a period of three months is manifest two years after the end of treatment. The roentgen doses were all small, so that no epilation appeared, even on the cranium, where most of the treatment was given, and treatment of such large fields with larger doses would hardly have been possible without grave effect on the whole organism. He believes that irradiation was the curative factor, because the processes in the cranium were still developing while the other affected places were being treated and did not subside until sufficient treatment had been given locally.

## CLASSIFICATION AND TREATMENT OF THE HEMORRHAGIC STATES

VALUE OF ROENTGEN IRRADIATION OF THE SPLEEN  
IN ESSENTIAL THROMBOCYTOPENIC  
PURPURA HAEMORRHAGICA

STACY R. METTIER, M.D.  
WITH THE TECHNICAL ASSISTANCE OF  
KATHERINE PURVIANCE, A.B.  
SAN FRANCISCO

Werlhof<sup>1</sup> first published his description of "morbus maculosus haemorrhagicus" in 1775, but knowledge concerning the nature of hemorrhagic disease has been slow in advancement. Since his publication, many attempts have been made to segregate various clinical types of purpura and to define their relationship to a defect in the clotting mechanism. Although efforts to explain the many etiologic factors concerned and the particular defect involved have not been entirely successful, certain aspects have been clarified by recent contributions to hematology. In view of the additional new facts, the present discussion will be devoted to a partial reclassification of the hemorrhagic disorders and to methods of treatment.

### CLASSIFICATION OF THE HEMORRHAGIC STATES

Hornung<sup>2</sup> in 1734 divided purpura into three groups: purpura simplex, febrile purpura, and purpura scorbutica. Since then from time to time various attempts have been made to subdivide purpura into clinical entities. Among these endeavors may be mentioned the contributions of Willan,<sup>3</sup> Schönlein,<sup>4</sup> Henoch,<sup>5</sup> Morawitz<sup>6</sup> and Kugelmass.<sup>7</sup> At present it must be recognized that the difficulties inherent in the problem of bleeding and blood clotting offer limitations in constructing an entirely satisfactory classification of the hemorrhagic states. Pepper and Farley,<sup>8</sup> in their textbook on hematology, give a clearer concept of the fundamental factors involved by means of a classification based largely on a deficiency of certain elements

essential to coagulation. A classification from a clinical point of view may be made, as in the accompanying tabulation, depending on the defect in the clotting mechanism or the vascular tree.

In addition to a carefully taken history of the course of illness and a thorough physical examination, laboratory aid is necessary for the diagnosis of hemorrhagic diseases. The laboratory procedures should include, as recorded in figure 1, the red blood cell count and hemoglobin concentration, the hematocrit determination, and the white blood cell and differential counts. These are done to determine whether or not anemia is present, and its type if present; whether the bone marrow is showing changes characteristic of leukemia or of one of the leukemoid processes. In all types of hemorrhagic disease it is especially important to enumerate the platelets and to determine the bleeding time and the time required for a specimen of blood to coagulate and to retract. In addition to these, it may be necessary to determine the fibrinogen content of the blood plasma and the degree of resistance or fragility of the platelets as evidenced by the prothrombin time.

In recent years it has become more and more apparent<sup>9</sup> that lessened capillary resistance or increased fragility is associated with spontaneous bleeding into the skin. An estimation of the capillary resistance may be made by the so-called Hess,<sup>9</sup> Rumpel-Leede<sup>10</sup> or tourniquet test. A modification of this is the flicking test. If a more accurate estimation is required, the Dalldorf<sup>11</sup> apparatus may be employed, and the number of petechiae produced under negative pressure in a small area may be counted.

In all types of hemorrhagic disease resulting from decreased formation of platelets, the bleeding time is increased, capillary hemorrhages appear in the skin following slight trauma or venous stasis, and there is a failure of the clot to retract. The clot is formed within normal time. There may be considerable variability between the degree of capillary resistance and the platelet level. Some patients exhibit markedly increased permeability of the capillaries, although the number of platelets is well above 100,000 per cubic millimeter of blood.

Since specific nutritional elements are needed to maintain the integrity of capillaries<sup>12</sup> and to form liver and blood proteins, a detailed history of the dietary habits of the patient should be recorded.

On the basis of the information gained with regard to a familial hemorrhagic tendency, the physical signs and

the abnormalities of the blood, the hemorrhagic diseases may be classified, within limitations, as in the tabulation.

The actual cause of platelet deficiency in a given patient may be undetermined. Accordingly these may be designated as idiopathic or essential thrombocytopenia. Certain investigators are of the opinion that the

### Classification of Hemorrhagic Diseases

- I. Deficiency in blood-clotting elements
  - A. Thrombocytopenic purpura
    1. Essential (idiopathic)
      - a. Splenic
      - b. Ovarian (David's disease)
      - c. Deficiency in megakaryocytes
      - d. Allergic (focal infections, drugs)
    2. Symptomatic
      - a. Bone-marrow destruction
        - Aplastic anemia
        - Leukemia
        - Myelophthisic anemia
        - Arsenic intoxication
        - Benzene
        - Radium
        - X-rays
        - Septicemia
  - B. Fibrinogen
    1. Liver disease (cirrhosis, chloroform and phosphorus poisoning, leukemia)
  - C. Calcium
- II. Abnormality in blood-clotting elements
  - A. Obstructive jaundice (cysteine)
  1. Qualitative alteration of fibrinogen
  - B. Hemophilia
    1. Qualitative blood platelet deficiency
- III. Defect in vascular mechanism
  - A. Allergy
    1. Schönlein-Henoch's purpura
    2. Focal infection
  - B. Nutritional
    1. Scurvy (vitamin C deficiency)
    2. ? Protein deficiency
  - C. Infectious diseases
    1. Subacute bacterial endocarditis
    2. Acute infectious diseases
  - D. Arteriosclerosis
  - E. Toxic (snake venom, histamine, quinine, potassium iodide, phenolphthalein)
  - F. Congenital
    1. Hereditary hemorrhagic telangiectasia

spleen is responsible for the platelet deficiency, by actually destroying these elements of the blood,<sup>13</sup> by removing them by phagocytosis, or through some regulatory influence exerted on the megakaryocytes in the bone marrow.<sup>14</sup> Others<sup>15</sup> believe that severe bleeding from the mucous membranes may be associated with a deficiency of ovarian hormone and concomitantly with a reduction in the circulating platelets.

The relationship between the megakaryocyte and the formation of platelets is still a matter of controversy. In a recent study on patients with idiopathic thrombocytopenic purpura, Lawrence<sup>16</sup> found that in this disease the bone marrow may present no abnormal morphologic characteristics or the megakaryocytes may be abnormal. Further studies such as his, by biopsy methods, are indeed indicated in this disease. Should the megakaryocyte in time be definitely proved to be the precursor of the platelet, a more satisfactory explanation may be offered of depressed marrow function, especially that occurring in association with certain allergic phenomena and infectious diseases and following the ingestion of certain drugs.<sup>17</sup> However, it is well recog-

nized that malignant neoplasms, leukemia, septicemia, arsenic, benzene, x-rays and radium may depress platelet production either through mechanical or through chemical destruction of the bone marrow.

In the presence of marked destruction of hepatic tissue or obstructive jaundice the blood fibrinogen may be quantitatively or qualitatively altered. Although formerly it was thought that calcium deficiency was responsible for the bleeding tendency of the jaundiced patient, it has been shown by Carr and Foote<sup>18</sup> that no important quantitative change in the clotting elements occurs but that the quality of fibrinogen and fibrin is definitely altered. These investigators believe that this is due to an accumulation in the blood of incompletely metabolized products of proteins, probably cysteine and its related mercaptans.

The relationship between the vascular system and an increased tendency to hemorrhage has not been adequately studied. It is presumed that the minute capillaries become weakened by sensitization through some bacterial product or drug and thus exhibit an allergic state. Often during the course of infectious diseases—epidemic meningitis, typhoid—petechial hemorrhages appear in the skin through interaction of the bacterial toxin on the endothelial structures or by actual lodgment of bacterial emboli. When the arterioles are altered by arteriosclerotic changes, they may be easily ruptured following slight trauma and thus account for ecchymoses found on the backs of the hands of elderly persons.

Further than this, easy bruising should make one think of a deficiency in vitamin C. It is now well recognized that subclinical scurvy<sup>19</sup> may exist without

evidence of gross subcutaneous or subperiosteal hemorrhages and may be suspected in a person subsisting on an inadequate diet. Case 1 is an example of this:

CASE 1.—Subclinical scurvy; hypochromic anemia; menopausal psychosis.

History.—K. R., a widowed Irish woman, aged 46, entered the San Francisco Hospital April 15, 1935, in the service of Dr. L. H. Briggs, because of weakness and dizziness. For two years prior to entry, a variety of complaints had developed among which were almost constant occipital headache and vague pains in the left side of the body, the left arm, left leg and left side of the chest. An intractable insomnia had developed and she had noted hot and cold flushes passing over her body. Her menstrual periods had become slightly irregular.

the flow more profuse than formerly. For ten years her dietary habits had been improper but during the past two years had been exceptionally so because of anorexia. Her breakfasts consisted of rolled oats with a small amount of milk and coffee, and for lunch she usually ate two or three slices of bread with the addition, about once or twice a week, of a helping of lima beans. The evening meal was usually more liberal

Fig. 2 (case 1).—Petechial hemorrhages on the forearm of patient with subclinical scurvy as result of positive test with tourniquet.

and consisted of soup and potatoes, cooked carrots or lima beans about twice a week, one slice of tomato about once in two weeks, and ham or corned beef every Sunday. She has neither cared for, nor does she eat, oranges or other fresh fruits and vegetables.

**Examination.**—The patient appeared slightly undernourished, in no obvious distress but with definite evidence of diminished mental acuity. The skin was pale, warm and moist, and there was no evidence of eruptions. The mouth was edentulous, and the tongue was slightly glossy and smooth but not tender. There was no lymphadenopathy. Neither the spleen nor the liver was enlarged. There was no edema of the ankles.

**Laboratory Procedures.**—The test meal revealed an achlorhydria. The blood examination showed red blood cells 3,300,000, hemoglobin 50 per cent (7 Gm.), color index 0.59 and leukocytes 3,850, with a normal differential count. The bleeding time was three minutes, and the platelets were 160,000 per cubic millimeter. A specimen of blood clotted in five minutes (method of Lee and White) and showed normal retraction. The sphygmomanometer cuff was applied above the elbow and inflated to just below systolic pressure. At the end of five minutes a shower of petechial hemorrhages appeared down the forearm, and about seventy-five were counted in an area 2.5 cm. in diameter. This is considered a definitely positive result of the tourniquet test.

**Course of Illness.**—A diet consisting of boiled milk and crackers was prescribed for the patient in order to eliminate the ingestion of foods containing vitamin C. She was given daily intravenous injections of 150 mg. of the sodium salt of cevitamic acid. On the fourth day of treatment the sphygmomanometer cuff was again applied to the arm and inflated, but very few petechiae appeared. This was considered a negative result of the tourniquet test. Figure 2 is a reproduction of a photograph showing the petechial hemorrhages that appeared in response to the tourniquet test prior to the treatment with the sodium salt of cevitamic acid, and figure 3 shows the result of a negative test four days later.

#### TREATMENT OF THE HEMORRHAGIC DISEASES

The foregoing is an example of the satisfactory treatment of subclinical scurvy with the sodium salt of cevitamic acid.

With regard to idiopathic thrombocytopenic purpura haemorrhagica, various methods of therapy have been suggested as being beneficial in the control of bleeding. Among the various drugs that have been used with supposedly beneficial results may be mentioned shock therapy with foreign protein, liver extract<sup>20</sup> both by mouth and parenterally, iron, ergot, snake venom<sup>21</sup> and cevitamic acid. Frequently more than one factor is operative in the causation of the hemorrhagic tendency, and the bleeding represents a summation of the various abnormalities. Accordingly, various methods of therapy must be used before satisfactory results may be expected. A dietary regimen has been suggested by Jones and Tocantins<sup>22</sup> and by Kugelmass<sup>7</sup> for patients who have had an inadequate intake of protein and foods containing vitamin C. In cases of mild purpura associated with a focus of infection, a permanent cure often follows the removal of the source of infection. Undoubtedly frequent transfusions of whole blood are of value in ameliorating symptoms in fulminating cases

Fig. 3 (case 1).—The forearm after four daily injections of the sodium salt of cevitamic acid. Note the fading petechiae and the failure of new ones to appear following the application of the tourniquet. (The larger pigmented areas are sites of venipuncture.)

of purpura. Removal of the spleen by surgical means is not entirely satisfactory. The mortality rate is high and a high percentage of patients have a recurrence of symptoms.<sup>23</sup>

23. Kracke, R. R.: The Effect of Splenectomy in the Purpuric Diseases, *South. Surgeon* 2: 203-211 (Sept.) 1933.

In 1920 Stephan<sup>17</sup> presented evidence showing cessation of hemorrhage in two patients with purpura fulminans following roentgen irradiation of the spleen. This was corroborated two years later by Bucky and Guggenheimer,<sup>24</sup> who additionally demonstrated a rise in blood platelets after this method of treatment. Since then there have been additional reports<sup>25</sup> in the literature emphasizing the usefulness of roentgen irradiation in patients with thrombocytopenic purpura haemorrhagica. Recently, Mettier, Stone and Purviance<sup>26</sup> concluded that a rapid rise in blood platelets occurred following irradiation of the spleen in five patients with this disease. Seven patients comprised the group for study. One patient died while under observation from an acute fulminating type of purpura. In another patient with chronic recurring purpura of two years' duration, splenectomy had been performed several months prior to roentgen irradiation. This patient subsequently had a recurrence of symptoms and on this

Fig. 4 (case 2).—Effect of roentgen irradiation over the spleen in a patient with thrombocytopenic purpura haemorrhagica. Note the rapid increase of the blood platelets.

occasion radiation was directed over the long bones. It was observed in the other five patients receiving treatment over the spleen and the patient receiving radiation over the long bones that an increase in circulating blood platelets was evident within from twenty-four to forty-eight hours after the first exposure to the roentgen rays. The platelets rose to as high as 250,000 and 500,000 per cubic millimeter in nine days, depending on the individual case. Treatments were given daily or every other day in doses of 200 roentgens until a total of from 1,200 to 3,300 roentgens was administered.

Since this report there has been an opportunity to observe an additional case, which may be reported as follows:

**CASE 2.**—*Recurring essential thrombocytopenic purpura haemorrhagica; hypochromic anemia.*

**History.**—C. H., a white American woman, aged 32, first visited her physician Aug. 4, 1935, complaining of bruising easily with slight trauma, bleeding from the gums and nose, profuse menses and generalized petechial hemorrhages in the skin and mucous membranes. In the past she had been well except for an attack of acute catarrhal jaundice five years previously. For many years she had been subject to frequent attacks of allergic dermatitis, and it was of interest to note

that there was a familial history of asthma on the maternal side. She stated that she did not use any drugs except an occasional tablet of acetylsalicylic acid and that her diet included an abundance of fresh fruit and vegetables.

**Examination.**—The patient appeared fairly well nourished and developed. There were small purpuric spots distributed over the body and some oozing of blood from the gums. There was no demonstrable lymphadenopathy, and the spleen was not palpable; other than this, the physical examination showed no abnormalities.

Examination of the blood showed erythrocytes 4,280,000 per cubic millimeter, white blood cells 5,200 and a hemoglobin concentration of 78 per cent. The bleeding time was over fifteen minutes and the coagulating time, with a capillary tube, was eight minutes.

**Course of Illness.**—The patient was observed over a period of approximately five months, during which time she received on different occasions transfusions each of 500 cc. of whole blood, injections of calcium chloride, a diet rich in vitamin C, and finally injections of moccasin snake venom. During this time there were remissions and exacerbations of her illness, but at no time was she free of a hemorrhagic tendency.

Jan. 14, 1936, the patient was admitted to the University of California Hospital. The abnormal physical manifestations were essentially those just reported, and the patient showed spontaneous hemorrhages into the skin and mucous membranes. The spleen could not be palpated, and there were no obvious foci of infection.

The examination of the blood, as recorded in figure 1, showed erythrocytes 3,760,000 per cubic millimeter, a hemoglobin concentration of 40 per cent (Sahli) (5.6 Gm.), reticulocytes 4.6, platelets 5 per hundred white blood cells in the stained film, and 80,000 per cubic millimeter by actual count. Following a small puncture wound in the ear, bleeding continued after fifteen minutes. A specimen of blood clotted in nine minutes, but there was failure of the clot to retract.

**Course of Illness and Therapy.**—The patient was given daily roentgen irradiation over the splenic area in doses of 200 roentgens until she had received a total of 1,400 roentgens. On the fourth day of treatment the platelets had risen to 135,000 per cubic millimeter and on the seventh day were approximately 300,000. Coincidentally, there was a cessation of spontaneous bleeding; the clotting time was reduced to five minutes and normal retraction occurred. The bleeding time was six minutes. In figure 4 are shown a summary of the treatment and a graphic presentation of the number of platelets for a period of three months after roentgen irradiation was first given to the patient.

#### SUMMARY AND CONCLUSIONS

If a careful history is taken to discover a familial hemorrhagic tendency, the dietary habits of the patient, the presence of recent infection or the use of marrow-depressing drugs, and if the blood is studied correctly in conjunction with determination of the permeability of the capillaries, a case of purpura can almost always be properly classified.

In planning satisfactory treatment, all these factors must be properly evaluated. Repeated roentgen irradiation over the spleen in suitable dosage is an excellent means of increasing the number of circulating blood platelets in patients with idiopathic thrombocytopenic purpura haemorrhagica.

#### ABSTRACT OF DISCUSSION

DR. E. B. REED, Lincoln, Neb.: I wish to ask the author how long his patients remained well after irradiation.

DR. STACY R. METTIER, San Francisco: The first patient was treated in April, two years ago. She had a recurrence four months later, was treated again and has remained well since. I have seen her at monthly intervals. Her platelets have remained within 300,000 per cubic millimeter and she has had no recurrence of the hemorrhagic phenomena. One other patient, following treatment, has remained well for about eighteen months, and another patient for about fifteen months. These are the patients I have had the opportunity of studying longest.

THE TREATMENT OF ENCAPSULATED  
BRAIN ABSCESS

EDGAR A. KAHN, M.D.

ANN ARBOR, MICH.

Although there has been advance in the treatment of brain abscess by modern methods, the mortality still remains strikingly higher than that reported by Macewen<sup>1</sup> in 1893. In recent years my associates and I have been using with slight modifications the method described by King<sup>2</sup> in 1924. This consists of direct transcortical exposure of the abscess, uncapping the presenting wall and packing of the cavity in one stage. The increased intracranial pressure then theoretically everts the abscess wall. Though we feel that this is the best method to date, we have had our share of failures, owing chiefly to technical difficulties arising in the treatment of deep-seated abscesses.

The first of these difficulties lies in the fact that though the overlying brain is removed in the exposure of the abscess capsule there is still considerable trauma to the adjacent brain. The latter is not removed and may predispose to purulent encephalitis. Secondly, when the capsule in a deep-seated abscess is opened either advertently or inadvertently, collapse of the capsule may occur with loculation and consequent reformation of the abscess. Especially is this true with thin-walled abscesses. Thirdly, even though the abscess is successfully drained the intracranial pressure may return so quickly to normal that the abscess capsule is not extruded, and healing results with extensive scar formation. A new method described by King<sup>3</sup> in which the gauze packing becomes adherent to the wall and aids in its eversion might tend to obviate this. In our experience the percentage of epilepsy following the drainage of brain abscesses has been exceedingly high and we believe it has usually been due to massive scar tissue.

A method which would bring the abscess to the surface where it could be easily drained or removed, thus minimizing the difficulties mentioned, was suggested by the following case:

CASE 1.—G. C., a 15 year old boy, entered the University Hospital June 21, 1933, with a history that he had always been well until December 1932, when he had an infection of the upper respiratory tract lasting about three days. This was followed by swelling of the right eye and right side of the face and neck. This was accompanied by headache, nausea and vomiting, and elevation of temperature. The headache had gradually increased up to the time of admission, and there had developed some photophobia and stiffness of the neck.

On examination the fundi showed bilateral papilledema of 2.5 diopters without hemorrhages or exudate. The visual fields were normal. There was slight rigidity of the neck, but Brudzinski's sign was negative. There were no cranial nerve palsies. The abdominal reflexes were present and all deep tendon reflexes were equal and active. There were no abnormal cerebellar signs. X-ray studies of the head revealed slight separation of the suture lines, convolutional atrophy and destruction of the dorsum sellae. There was no abnormal calcification. The paranasal sinuses were negative except for a slight loss of sharpness in the superior margin of the right frontal sinus.

From the Department of Surgery, University Hospital, clinic of Dr. Max M. Peet.

Read before the Section on Nervous and Mental Diseases at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 13, 1936.

2. King, J. E. J.: *The Treatment of Brain Abscess by Unroofing and Temporary Herniation of Abscess Cavity with the Avoidance of Usual Drainage Methods*, Surg., Gynec. & Obst. 39: 554 (Nov.) 1924.

3. King, J. E. J.: Personal communication to the author, Nov. 22, 1935.

The white blood count was 15,000, the hemoglobin 85 per cent. The urine was normal and the blood Kahn reaction negative. A diagnosis was made of probable right frontal abscess. A ventricular air injection was performed to establish definitely the location of the lesion. Only a few cubic centimeters of air could be instilled. The left frontal horn was seen to be displaced to the left; the right frontal horn was not visualized.

The following day a trephine opening was made over the right frontal lobe. On exploration with a cannula no lesion was encountered. It was then felt that a right frontal tumor was present. Accordingly, a right sided frontoparietal osteoplastic flap was turned down. The dura was opened and no surface abnormality seen. A cannula was passed deep into the frontal lobe and an abscess cavity entered. As soon as the pus appeared the needle was withdrawn. Bone was removed from the bone flap for an area the size of a silver dollar (38 mm.) directly over the puncture wound. The dura was left open here and it was hoped that the subarachnoid space would become obliterated and the abscess become more superficial. The bone flap was replaced and the scalp was closed in the usual manner except for an area over the bony defect. An iodoform pack was placed through the scalp and bony defect directly on the cortex. The sutures were removed on the fourth day after operation, the wound remaining clean. On the ninth postoperative day the patient was returned to the operating room. The cortex was clean and bulged slightly. The abscess was tapped. It had become much more superficial. The edematous brain overlying the cortex was removed with the electric loop. The capsule was opened and a pack easily placed within. Because of the marked thickness of the wall, the fact that the abscess was so superficial and the subarachnoid space so well sealed off, it was decided to remove the entire capsule. This was easily accomplished with traction and wiping with cotton pledgets, but at the last moment a small hole was made in the ventricle. Though this was easily seen and a muscle graft was inserted, a cerebrospinal fluid leak developed in five days and the patient died of meningitis at the end of two weeks.

This case was unfortunate in its handling from start to finish. However it was demonstrated that an encapsulated abscess would rise toward the surface were a decompression made over it, in the presence of increased intracranial pressure.

CASE 2.—L. M., a youth, aged 17 years, was admitted to the University Hospital July 26, 1935, with a history that five weeks previously he had noted the onset of severe left frontal headache with swelling of the tissues about the left eye. A slight coryza persisted for several days, the patient having been sufficiently ill to remain at bed rest for six days. The headache had disappeared for five days following its onset but had recurred and persisted up to the date of admission.

The patient was well developed and was not acutely ill but was obviously suffering headache. The left palpebral fissure was smaller than the right. There was a bilateral papilledema of 2 diopters without hemorrhages. The visual fields were normal. There was a slight right sided facial palsy of central type. The neurologic examination was otherwise entirely negative. X-ray studies of the skull revealed clouding of the left frontal sinus with evidence of destruction along its superior margin. The white blood count was 11,300 per cubic millimeter; the hemoglobin was 86 per cent. A diagnosis was made of osteomyelitis of the left frontal bone with underlying brain abscess. In view of the patient's comparatively good condition it was felt that the infected bone should be first removed and the epidural space explored. Accordingly, a left Killian and left external ethmoidectomy was performed by Dr. J. H. Maxwell, August 6. The left frontal sinus was found to be filled with pus and purulent granulation tissue. There was an osteomyelitis of the anterior table of the frontal sinus with a very extensive dural exposure from necrosis of the inner table. The dura was covered with thick, purulent granulation tissue. A complete Killian operation was done. The floor of the frontal sinus was removed. A narrow supra-orbital bridge was left in place. The dura was definitely tenser than normal. The infection had extended to the right frontal sinus so that the entire partition between the two frontal sinuses was removed and part of the anterior table of the right frontal sinus. Following this, a complete exenteration of the ethmoid sinuses

by the external route was performed. Convalescence was uneventful. The headache persisted, however, and the papilledema increased slightly.

September 4, under local anesthesia, a transverse incision was made about 2 inches above the left eyebrow. An opening was made in the left frontal bone about the size of a silver dollar. The dura was opened. The subarachnoid space was not sealed off. This was obliterated as well as possible by electrocoagulation. There was slight brain herniation. The abscess wall was felt with the exploring needle at about 2.5 cm. The abscess cavity was not entered. The needle was immediately removed and an iodoform pack was loosely placed over the brain substance. No rise in temperature followed this procedure.

September 7, under nitrous oxide anesthesia, the iodoform pack was removed. A moderate herniation of edematous brain was present. This was easily removed by suction. The firm

Fig. 1.—Patient 3, showing operative site six months after operation.

abscess capsule was seen to be flush with the skull defect. The abscess wall was opened with the electric loop. It was fully one-eighth inch (3 mm.) in thickness. By traction and careful dissection the entire abscess wall, which was the size of a hen's egg, was removed. The cavity remaining was seen to be entirely sealed off from the general subdural and subarachnoid spaces. A small gauze pack moistened with metaphen in oil was placed here. Three days after operation the cavity remaining after excision of the abscess had obliterated itself. The patient's condition improved rapidly. There was a small amount of purulent discharge. A slight herniation developed. In retrospect we realize that this should have been prevented by lumbar puncture. This would have hurried healing and prevented the cerebrospinal fluid leak which subsequently developed. This cerebrospinal fluid leak appeared exactly three weeks after operation. A lumbar puncture was performed and the needle left in place for three hours. Dehydration with sucrose and limitation of fluids was commenced. When the patient was dressed the following day it was found that the gauze which was covering the brain herniation had been actually drawn into the cranial cavity through the defect in the skull, because of its adherence to the retreating brain substance. It was extricated with some difficulty. Lumbar drainage was again performed the following day. There never again was any cerebrospinal fluid discharge. The dehydration was kept up for one week, when it was discontinued. Rapid epithelization now took place, and the patient was discharged October 14

with only a small area the size of a dime (18 mm.) which had not epithelized. Two weeks later the patient returned to check up with the wound perfectly healed. A letter was received from the patient April 10, 1936, stating that he was perfectly well and symptom free.

This case again shows that an encapsulated abscess can migrate toward the surface beneath a decompression, in the presence of increased intracranial pressure. A fairly deep abscess has here been brought to the surface, where it could have been easily and safely drained had we not chosen to remove it.

CASE 3.—W. L., a laborer, aged 20, entered the University Hospital Oct. 22, 1935, in a semicomatose condition. There had been a history of pain over the left frontal region since early July. The patient's physician stated that the left frontal and maxillary sinuses were cloudy on transillumination. There had been no nausea, vomiting or generalized headache, and there was no history of acute infection.

October 8, because of the persistent pain, an operation was performed elsewhere under general anesthesia in which "the anterior tip of the middle turbinate on the left side and a few anterior ethmoid cells were removed. No pus was seen." The patient's condition seemed to improve until October 21, when his headache again became very severe, and the night following he could not be aroused. He was accordingly transported to this hospital.

The patient was dehydrated, semistuporous, incontinent and hiccuping frequently. The fundi showed bilateral papilledema of 2 to 3 diopters with hemorrhages. There was slight stiffness of the neck, but Kernig's sign was negative. There was no facial paralysis. The right knee and achilles jerks were somewhat more active than the left. Babinski's sign was positive on the right. The white blood count was 26,000. The urine contained a small amount of albumin. The temperature was 100.8 F., the pulse was 72, and respirations were 16 and abnormally deep. Intravenous 50 per cent sucrose was given with some improvement in the patient's condition. The following day he was taken to the operating room. Because of his precarious condition it was felt that the abscess should be tapped immediately. Accordingly, a left sided trephine opening was made about 2 inches above the eyebrow. The abscess wall was encountered at about 2.5 cm. It was entered and thick, greenish pus later proved to contain *Staphylococcus aureus* was evacuated. Approximately an ounce (30 cc.) was removed. Purposely no attempt was made to evacuate the abscess. The bone defect was then enlarged to the size of a silver dollar (38 mm.) and the dura widely opened. The surface vessels were coagulated and the subarachnoid space sealed off. An iodoform pack was placed over the cortex. The following day the patient's condition was greatly improved. Five days later the patient was taken to the operating room and placed under nitrous oxide anesthesia. It was seen that there was a brain herniation of approximately 3 cm. The edematous brain was removed by suction and was no more than 1 cm. in thickness. The thick abscess capsule was then seen. It projected at least 2 cm. above the bone defect. The abscess capsule was opened. By means of traction and careful dissection with cotton pledgets the entire abscess wall was removed except for a narrow stalk about 3 mm. in diameter which ran down into the brain substance. The stalk was cauterized. A surprisingly small cavity remained. The subarachnoid and subdural spaces were apparently entirely sealed off. A small pack of gauze wet with metaphen in oil was placed within the cavity. Several stitches at the outer margins of the scalp incision were taken.

The temperature reached 104 rectally the day of operation but within two days was practically normal and remained so. The patient's general condition improved rapidly. Eight days later, under ether anesthesia, a left sided Killian operation was performed by Dr. A. C. Furstenberg. The anterior wall of the left frontal sinus was removed. The thickened, inflamed lining mucous membrane was immediately seen to be covering the dura. Dr. Furstenberg remarked that it was of unusual interest to observe that the inner wall of the frontal sinus had been destroyed to such an extent that there were not even sequestrums present and the dura and brain had pushed forward, completely filling the frontal sinus. The inner wall of

the frontal sinus on the right side was present, and the cavity was perfectly clean. A fairly complete exenteration of the ethmoids was done and the sphenoid sinus explored. The latter was found to be normal. The ethmoids were the seat of inflammatory and polypoid mucous membrane, but there was no pus present. The fronto-ethmoid cells were completely exenterated and free communication was established between the left frontal sinus and the nose. The left frontal sinus, however, was only a potential cavity because it was completely filled with brain covered by dura. The ethmoidal area and frontonasal duct were packed with petrolatum gauze and the incision was closed for primary union. The wound healed satisfactorily.

The brain abscess wound, in the meantime, was healing in exactly the same manner as was described in the previous case. A slight herniation developed. Again, in retrospect, we realize that this should have been prevented by lumbar puncture. Exactly eighteen days from the date of excision of the brain abscess, a cerebrospinal fluid leak developed from the center of the granulating tissue. Lumbar drainage was immediately performed. Intravenous 50 per cent sucrose was given, and dehydration commenced with complete limitation of fluid. The following day cerebrospinal fluid was again seen. Lumbar drainage was performed for four hours in the morning and two hours in the evening. The temperature rose to 101.6. Cerebrospinal fluid never appeared again. No further lumbar punctures were done. Three days after the last puncture, the patient having been kept on strict dehydration, a large cavity was seen beneath the bone defect. Fluids were immediately recommenced. Within a few days clean granulation tissue had filled the skull defect. Ultraviolet rays were now given locally to stimulate healing. The patient was discharged December 14 with the wound practically healed. Jan. 18, 1936, he returned because of an attack of generalized convulsions. Shortly afterward a soft tissue abscess was evacuated at the site of the previous sinus operation. The patient was seen April 18 (fig. 1) stating that there had been no further convulsions and that he was entirely symptom free. The neurologic examination was negative. Pulsation was present over the scar.

Again is seen how closely case 2 has been paralleled. The patient's precarious condition, however, made partial evacuation of the abscess necessary before the bony focus was excised.

CASE 4.—J. A., a youth, aged 20 years, entered the University Hospital Sept. 17, 1935, with a diagnosis of pansinusitis and osteomyelitis of the anterior wall of the left frontal sinus. Brain abscess was suspected at this time because of previous headache and vomiting. The fundus examination was negative, as was the neurologic study. The patient did not appear in any way acutely ill. A bilateral Killian operation was performed. There was osteomyelitis of the inner table of the left frontal sinus as well as of the left frontal supra-orbital ridge. The dura on exposure was found to be thickened, and brain abscess was suspected beneath. Following this operation the patient's symptoms cleared up rapidly, and though abscess was still suspected he was discharged to return should symptoms of a cerebral lesion reappear. The patient was again seen December 10. There was bilateral papilledema of 4 diopters with hemorrhages. The visual fields were normal, as was the remainder of the neurologic examination except for a slight bilateral sixth nerve palsy. The white blood count was 12,800. A left frontal abscess was suspected. December 14, through a trephine opening just back of the hair line in the left frontal area, the abscess wall was palpated at a depth of exactly 3.5 cm. from the brain surface. The decompression was enlarged to the size of a silver dollar (38 mm.). The surface vessels were coagulated and the arachnoid sealed to the cortex. Three days later there was brain herniation over the defect of about 2.5 cm. The edematous brain was removed by suction down through the skull defect. The abscess capsule was seen 0.5 cm. beneath the inner wall of the anterior margin of the defect. Two days later a small amount of edematous brain had risen above the defect. This was sucked away and it was now found that the firm capsule had risen 0.5 cm. above the outer surface of the skull. No rise in temperature and no symptoms followed either of these procedures. The following day the abscess ruptured spontaneously. The capsule, however, remained at

the surface. The dome of the capsule was then excised and an iodoform pack placed within the cavity. The day after, cerebrospinal fluid was seen coming from the subarachnoid space at the edge of the wound. In spite of the presence of pus in the vicinity, lumbar drainage was performed and dehydration commenced. The wound was left exposed and was frequently irrigated with metaphen. There was no further escape of cerebrospinal fluid, and from then on convalescence was entirely uneventful. The patient was discharged five weeks later with the wound almost entirely healed. A letter dated April 8 stated that the patient was entirely well and symptom free.

At the time of excision of the dome of the capsule the dissection must have been carried too far laterally, thus opening the subarachnoid space. It was not realized until the following day, when the escape of cerebrospinal fluid was seen. It should easily have been avoided.

#### TECHNIC

Preliminary to the drainage of any brain abscess the original bony focus, should one be present, is obliterated, provided the patient's condition permits. This means mastoidectomy, exenteration of paranasal sinuses, or excision of other areas of osteomyelitis of the skull. Theoretically this should prevent reinfection after the abscess has been dealt with and at the same time excludes epidural abscess as a cause for the symptoms. From one to two weeks after this procedure, depending on the state of the wound and the condition of the patient, a trephine opening is made over the suspected area. (If possible, an abscess should be attacked where it is closest to the surface. McKenzie<sup>4</sup> has stressed that where the abscess is encountered obliquely to the exploring needle a new opening should be made over what is visualized as the most superficial part of the abscess.) The dura is opened and a dull exploring cannula is passed through the cortex in the direction of the abscess. When the rubbery feel of the wall is encountered the cannula is withdrawn without piercing the capsule. The bone opening is then enlarged to about the size of a silver dollar (38 mm.). The dura is further opened in a stellate manner. The brain then herniates slightly. The surface vessels are coagulated and the arachnoid sealed to the cortex at the margins of the wound. An iodoform pack is placed to further the formation of adhesions, thus completely sealing off the subdural and subarachnoid spaces at the margins of the defect. One is still working in a sterile field. This procedure is performed under local anesthesia, as there is no desire at this stage to heighten the already increased intracranial pressure.

Fig. 2.—First stage: I, abscess wall palpated with cannula through trephine opening; II, opening in bone enlarged, dura opened, surface vessels and arachnoid coagulated. Second stage: III, four days later, showing migration of abscess and herniation of brain; IV, herniating brain removed by suction; abscess ready for drainage or excision.

4. McKenzie, K. G.: The Treatment of Abscess of the Brain, Arch. Surg. 18: 1594 (April) 1929.

The next stage is performed from three to four days later. The abscess capsule, if smooth walled and not bound down, will have migrated to the surface, covered by edematous brain. The latter is now easily removed by suction. If the abscess has not risen sufficiently above the surface, one can wait several days more and again remove any edematous brain covering the capsule. I believe that if one waits sufficiently long the abscess may completely extrude itself. Case 3, in which the abscess had migrated so that its dome was at least 2 cm. above the skull defect, illustrates this principle. The abscess would undoubtedly have completely delivered itself had sufficient time been given. At the time that the abscess is drained or excised nitrous oxide is used, since it is well known to increase the intracranial pressure. I feel that this aids in removal of the capsule or extrusion of its contents. If one prefers drainage to complete excision of the abscess it is probably best accomplished by cutting off the dome and stitching the walls to the subcutaneous tissues, as described by Horrax.<sup>5</sup>

The one important factor in the postoperative treatment is the prevention of brain herniation by lumbar puncture and dehydration, when necessary. King<sup>3</sup> has stressed this point in a personal communication and I am entirely in accord. Had the slight herniation that developed in cases 2 and 3 been prevented, healing would have taken place quicker and the cerebrospinal fluid leak which undoubtedly came from the ventricle would not have occurred. The fact that the leaks were so readily controlled in both cases by lumbar puncture and dehydration is good evidence that they could have been prevented.

#### SUMMARY

No attempt has been made to discuss the etiology, symptomatology and actual drainage of brain abscess. A procedure is merely given by which a chronic encapsulated brain abscess can be more easily dealt with. I have shown in these four cases that a brain abscess can migrate to the surface beneath a decompression, in the presence of increased intracranial pressure. Adson and Craig<sup>6</sup> have stated: "Cerebral abscesses are invariably situated below the cortex. Occasionally a stalk can be seen to extend from the meninges to the abscess, but, more often than not, no trace of invasion can be demonstrated." From this statement one may deduce that in most cases of encapsulated abscess there is nothing to prevent their changing position under certain pressure conditions. Could all abscesses be drained at the surface under circumstances which would minimize the possibility of meningitis, the mortality would undoubtedly diminish.

#### ABSTRACT OF DISCUSSION

DR. R. GLEN SPURLING, Louisville, Ky.: Dr. Kahn has made a valuable contribution to the treatment of deep seated, thick walled cerebral abscesses. I feel strongly that his method does not apply to the treatment of subacute abscesses. In my experience, during the subacute stage, the repeated tapping method of Dandy is preferable to any other. He has demonstrated a simple, effective way of promoting migration of the abscess to the surface before any attempt is made to establish drainage. My attempts to draw manually the wall of the abscess to the surface, after the contents have been evacuated, have often been successful and at other times most unsuccessful. Too frequently the wall is not dense enough to withstand the tugging required to accomplish this end. In such circumstances a tube drain is resorted to and, as a consequence, most of them

eventually refill, and the whole procedure has to be repeated. It has been my experience that, when the abscess wall can be stitched to the skin through an opening in the cerebral cortex, dura and bone sufficiently large to allow herniation of the capsule, the patient has an excellent chance to recover. Now that this method of handling the more deep seated ones has become available, the death rate from chronic cerebral abscesses should be still further reduced.

DR. JOSEPH E. J. KING, New York: Dr. Kahn's procedure is a contribution to the work on brain abscess. In 1924 when I described an operation for brain abscess it never occurred to me that a deep seated abscess could be herniated to the surface and treated in the manner suggested. I never proposed that the operation described by me could so be used. Now that Dr. Kahn has shown how to bring a certain number of abscesses to the surface, it makes me more hopeful in dealing with the deeper seated abscesses. It is remarkable how much interest has been shown in the subject of brain abscess during the last two decades. It is strange that there could have been such a lull after the splendid contribution by Sir William Macewen in 1893, and much that he taught seems to have been forgotten or overlooked until the last two decades. The mortality rate in cases of brain abscess will necessarily be rather high. Many rupture into the ventricle or into the meninges without having been previously recognized or localized. Some will do so after operation. Some very good series of recoveries have been reported, the largest being that of Adson and Craig. Grant, Coleman, Horrax, Cahill and others likewise have reported a number of recoveries. In Grant's rather large number of cases there were quite a few which did not even come to operation for one reason or another. The patients were too ill or were moribund. Therefore the mortality rate, taking all cases by and large, will necessarily be rather high. Adson and Craig's procedure is quite similar to the one described by me. Horrax and others have operated on abscesses when possible, with a rather wide open approach which allows of proper inspection of the cavity. Grant, Coleman and others continue to use a small drainage tube (catheter) through a small opening. Grant has devised a very ingenious instrument for introducing the catheter into the abscess. All have reported comparatively good results in operable cases. I have seen, excluding a number of traumatic brain fistulas, thirty-five cases of nonmetastatic abscesses and six cases metastatic in origin; so that there is no one operation for the treatment of brain abscesses, not only for the reason that they are not all alike but also because various types of operations have given fairly good results. There are a number of ways to enter this city, and one may be as good as another. I am grateful to Dr. Kahn for the information regarding deep abscesses. It will be of decided benefit. I am glad to know that he, Cairns and others have successfully used the procedure described by me. In my hands it has given fairly good results. I expect to continue its use.

DR. WALTER E. DANDY, Baltimore: I can't refrain from expressing very radical disagreement with this method of Dr. Kahn and Dr. King. To me a fungus, a wide open wound or a cerebrospinal fistula is a matter of horror. I feel strongly that surgeons do far too much in treating brain abscesses. There is one important rule in the treatment of any infection of the brain: to go slowly and do as little as possible; with abscesses that little is merely to relieve the intracranial pressure by tapping, not draining, the abscess. Nature will do the rest. Give nature a little time and a little well directed assistance with a single chronic brain abscess, and most of them will be cured without disfigurement, without fungus formation and without cerebrospinal leakage and the danger of meningitis. In my experience simple tapping has been far and away the best treatment in the handling of such abscesses. Unfortunately more abscesses of the brain are multiple than single, and then one has very different problems with which to contend. But a single abscess is really a very simple lesion to treat.

DR. TEMPLE FAY, Philadelphia: I believe that Dr. Kahn has really made a definite contribution to the treatment of brain abscess. Here are two illustrations from my experience: A boy, aged 16, was struck on the head by a bucket of coal falling 16 feet and sustained a compound fracture of the skull. The surgeon who attended the boy operated to remove the particles of bone, encountered active hemorrhage from the lateral sinus, packed the sinus, and eight days later attempted to remove the packing. Infection had occurred. Another hemorrhage fol-

6. Adson, A. W., and Craig, W. M.: The Surgical Management of Brain Abscess, *Ann. Surg.* 101: 7 (Jan.) 1935.

lowed, and the sinus was packed again. Thirty days later the patient was sent to my clinic with infection around the wound, a large open area from the decompression, and fungating brain, with a piece of packing extending down into the right parietal lobe. Because of the active infection in the wound we had no alternative and didn't dare to operate. We allowed the brain to herniate. I thought the boy was going to die. He was hemiplegic and stuporous. Transfusions were given and five weeks passed. I simply cut off the herniated portions of the brain. The abscess, including the packing, eventually extruded itself. To my amazement the boy recovered and is now attending school. He has fair use of his left side. He had a spontaneous recovery, and the wound was eventually closed. The second case, in a child of 6 years, was one in which I suspected a subdural abscess. I found a large subdural, infected hematoma with pus. I was afraid to leave the bone flap in place for fear there would be osteomyelitis. I removed the flap and, in so doing, accomplished what Dr. Kahn has already pointed out, decompressed the abscess. The boy today is ready to leave the hospital, although the abscess cavity contained 90 cc. of pus. I was extremely interested in what Dr. Kahn said about giving the anesthesia to help express the abscess. In the original work of Ambroise Paré is a fine account of a series of brain abscesses well treated. Perhaps in those days they let them go until, as Dr. Dandy said, they had become very focal processes, and nature does a great deal for them. But Ambroise Paré's method was to open the skull by trepan and insert a lead tube into the cavity. He naively states that each day, on dressing the patient, he required that the patient hold his nose, take a deep breath and strain so as to push forth the sanguineous material. That is the first record I have seen that deliberate attempts to increase intracranial pressure help evacuate an abscess or move these abscesses toward the surface. Dr. Kahn is to be congratulated for his well founded observations and method of treatment.

DR. JAMES RUDOLPH JAEGER, Denver: The less a brain abscess is disturbed, the better off the patient will be, provided adequate drainage is instituted. As Dr. Kahn has pointed out, many of these abscesses are very deep, going right up to the ventricle, and there is a very thin barrier between the abscess and the ventricle itself. There is no question that many abscesses extend into the lateral ventricle and fill the whole ventricle and yet the patient may recover.

DR. PERCIVAL BAILEY, Chicago: I would like to express the same horror of herniation. There are areas in the brain where one would hesitate to provide such hernias and certainly where one would hesitate to decompress such an abscess because of the resulting neurologic defects. In those cases I would call attention to the method recently devised and proposed by Vincent and his associates in Paris. He taps these abscesses repeatedly, as Dr. Dandy proposed, and, after weeks and months have elapsed, he deliberately goes in and extirpates the abscess as he would a tumor. Last summer he showed me a series of fifteen or twenty surgical specimens which he had treated and removed in this way. I was impressed by his results and have since then been handling abscesses in that way myself, with one exception. This abscess occurred in a boy who had osteomyelitis of the skull. A large portion of the skull had been removed. An abscess afterward developed directly underneath this area. An opening was made into the abscess through this area from which the skull had been removed. A drain was put in; herniation occurred, and the abscess extruded itself through this opening and was completely taken off, without any difficulty at all, as Dr. Kahn has stated. But that wasn't the end of it, because once the abscess was out the brain also came out and kept coming until the ventricle ruptured, and the cerebrospinal fluid poured out through this opening. Since the herniation occurred through the speech area, the boy was hemiplegic and aphasic as well. I am sure that if this abscess had been treated by tapping, simple tapping, it could afterward have been extirpated, if necessary, if it did not heal. Dr. Dandy suggests that they usually do; that has not been my experience. But if it had not healed, it could afterward have been extirpated as Vincent suggests, with considerably less defect to the patient than occurred in handling it in this way. Why the brain kept on coming out in this case I think was the fact that the boy had had some chronic meningeal inflammation which had disturbed the circulation of the spinal fluid, so that the pressure in the ventricles continued to rise. Repeated lumbar punctures had no influence in preventing the herniation.

DR. EDGAR A. KAHN, Ann Arbor, Mich.: I would like to answer Dr. Bailey first. Once the abscess is out there is no need for herniation in any cases I have seen, unless there is an underlying abscess, and it is very possible that that was a metastatic case.

DR. BAILEY: The boy is still alive. He is still draining cerebrospinal fluid and is hemiplegic and aphasic.

DR. KAHN: There is no reason why that herniation should continue. In these three cases, as soon as the abscess was extruded there was a cavity, but a surprisingly small cavity that filled in two or three days. The whole thing could have been easily controlled with lumbar punctures.

DR. BAILEY: We made encephalograms and ventriculograms, and we didn't find any evidence of another abscess. That doesn't prove it isn't there.

DR. KAHN: In answer to Dr. Dandy, I first make a trephine opening. I do not make a big opening. I tap first through this small trephine opening. If I find the abscess, I make a decompression no larger than a silver dollar (38 mm.). That does not give a big herniation. The abscess does come up. As for repeated tapplings curing these heavy, encapsulated abscesses with a virulent infection, I know of nobody else who has had the results that Dr. Dandy has had.

DR. FRANCIS C. GRANT, Philadelphia: May I interject at this moment that I have had five out of seven patients with encapsulated abscess recover from simple tapping.

DR. KAHN: I didn't realize that. But in the hands of other people I don't know that such results have occurred. This isn't a complicated method at all. It is used in the deep seated abscesses. I think one of the most technically difficult things is to get in and drain an abscess that lies from 2 to 3 cm. down.

## INSULIN SHOCK THERAPY IN SCHIZOPHRENIA

JULIUS STEINFELD, M.D.  
PEORIA, ILL.

Recently Sakel<sup>1</sup> and Dussik and Sakel<sup>2</sup> introduced insulin as a therapeutic agent in the shock treatment of schizophrenia. Their reported good results have been confirmed by Müller,<sup>3</sup> Wortis<sup>4</sup> and Wilson.<sup>5</sup> Glueck<sup>6</sup> has discussed the methods and importance of this new treatment as carried out at Münsingen, Switzerland. Gross<sup>7</sup> and Georgi<sup>8</sup> have studied the humoral changes during insulin shock.

A few months ago I began to use this treatment, employing the technic described by Dussik and Sakel.<sup>2</sup> Although I have observed only three cases, it seems worth while to relate my experiences because (a) this form of therapy is new and every contribution may be of some importance; (b) I have treated old rather than new cases, since it is difficult to evaluate and therefore to make allowances for the tendency to remission early in the course of the disease, and (c) I may emphasize the difficulties and hazards involved in the application of this treatment.

### REPORT OF CASES

CASE 1.—H. B., a woman, aged 27, had, eight years before, when she was a school teacher, developed a depression with

From the Michell Sanatorium.

The author is indebted to Dr. Heilbrunn, staff member of the State Hospital at Münsingen, Switzerland, for his suggestions regarding this form of therapy.

paranoid ideas. She left school, spent several months in a mental hospital and after two years made a spontaneous but, subjectively, only a partial recovery, since she continued to have strong feelings of guilt and mild depressions, usually during her menses. Her father and a maternal aunt have been treated in mental hospitals. She married five years after the onset of her illness and gave birth to a baby girl one year later. There is no history of marital unhappiness. The patient entered the sanatorium four months ago very much depressed. She complained of vague uncomfortable sensations and repeated constantly "I am losing my mind." Intervals of great excitement to the point of screaming and violence alternated with periods of deep depression, during which the patient refused to speak to or to look at any one. She exhibited several stereotyped gestures and grimaces and on a few occasions had visual hallucinations. At times she broke into foolish, causeless laughter. She refused to see any members of her family. Physical examination was essentially negative. There was a mild secondary anemia.

Insulin was given intramuscularly in an initial dose of 15 units. This was increased by from 5 to 10 units daily until a maximum of 95 units was reached. As the dosage mounted the patient occasionally exhibited short periods of somnolence, alternating with periods of excitement; accompanying the latter there were occasionally slightly increased perspiration and mild, generalized twitchings. The magnitude of the reaction was not directly proportional to the amount of insulin given, nor was it inversely proportional to the height of the blood sugar, which never fell below 40. The order in which the various signs of insulin shock might appear was absolutely unpredictable and completely irregular. At 95 units, after a period of intense excitement, a severe circulatory collapse suddenly developed without unconsciousness, in spite of the fact that the patient had been digitalized. She was given sugared tea by mouth, epinephrine and caffeine intramuscularly and dextrose intravenously. Her condition was critical for two hours; that evening her temperature rose to 102.2 F. During the following week only from 50 to 65 units was given, during which time the patient had periods of excitement and/or somnolence, although there were days on which the insulin had no apparent effect. The dose was then slowly increased, and at 75 units, after a period of light somnolence and very mild twitching, strong tonic and clonic convulsions suddenly developed and she went into a state of circulatory collapse, for which epinephrine, alpha-lobeline and intravenous dextrose were required. Thereafter, doses of from 50 to 60 units occasionally brought about similar but milder attacks. Great care was taken to give sugar early. There was never any profuse perspiration or salivation.

Throughout the course of the treatment and to a degree apparently unrelated to the severity of the reaction, it was possible to establish good contact with the patient for several hours at a time. As the end of the treatment was approached (after twenty-four insulin shocks) the patient showed a marked improvement; she happily awaited her husband's visits, chatted freely during his stay and showed great interest in her child. At present she is progressively becoming better adjusted to her environment. Her stereotyped mannerisms are less and less noticeable. She is eager and happy to see her family. Her emotions are labile and she laughs somewhat too freely. She exhibits a deep interest in the course of fellow patients to whom she had previously paid no attention. She is now ready to go home for convalescent care.

In contrast to this patient, who exhibited almost none of the typical reactions so carefully described by Dussik and Sakel, are patients 2 and 3, who are still being treated:

CASE 2.—P. Z., a man, aged 25, first exhibited some depressive signs about one year before admission. Marked paranoid symptoms developed two months before. On admission he was excited and violent and had all types of hallucinations. He showed marked improvement after a few weeks of physical therapy but suddenly suffered a complete relapse, during which even graver delusions developed than he had presented on entrance. Treatment was started with 20 units of insulin, and by the time 50 units had been reached the patient went through all the typical "phases" described by Sakel, the period of

"activated psychosis" always being preceded by one of profuse perspiration and a subjective feeling of great weakness. Although treatment of the patient is still in progress, it is evident that on awakening from the induced coma he is becoming increasingly more cooperative, and it is possible to establish good contact for progressively longer periods.

CASE 3.—M. X., a woman, aged 31, started in her psychosis six months ago with ideas that she was infected with syphilis and tuberculosis. At first the diagnosis of compulsion neurosis was made, but later it became evident that the patient was a paranoid schizophrenic. She felt that a certain man had hypnotized and infected her, and so on. The patient suffered greatly with her fixed hypochondriacal ideas, and it was impossible to convince her of their imaginary character. She has received ten treatments beginning with 15 units and increasing to 60 units; she has reacted with typical "wet" shocks. There have been marked cardiac irregularities in spite of digitalization. The patient's compulsive ideas tend to grow weaker during the hypoglycemic state and for some hours afterward, although it is obviously too early to draw any definite conclusions.

A complete report, including a discussion of the psychologic phenomena, will be made after a suitable period.

#### CONCLUSIONS

1. These patients differ not only from each other in the type of their reactions but also in the magnitude and type of their response to any given amount of insulin. The application of this treatment imperatively requires the constant presence of the physician and of efficient nurses, because of the hazards involved.

2. From my limited experience, insulin shock therapy may show many serious deviations from the typical reactions. In patient 1 there were no typical "wet shocks," and she never fell into deep somnolence or coma. At the point at which increasing somnolence or coma might be expected, this patient went into either severe epileptiform convulsions or a circulatory collapse so profound that immediate intervention was necessary. Blood sugar determinations proved to be of little value in predicting the course of the reaction; much more important was careful observation of the pulse and blood pressure.

3. In the cases reported I observed what Dussik and Sakel term "activated psychosis"; this manifests itself by such symptoms as increased restlessness, a tendency to violence and an exaggeration of all the presenting symptoms. The patients then went into actual shock; as they recovered from this the sensorium seemed to clear. During and after the treatment it seemed to be possible to influence the patients in a psychotherapeutic way. In my opinion too the type of reaction in patients 2 and 3 ("wet shock") is not as dangerous as that described in the first case.

4. Patient 1 first developed psychotic symptoms eight years ago; this initial attack lasted two years. It was possible to bring this patient, refractory to all other forms of therapy, out of her psychosis in seven weeks and send her home. This period is to be compared to her first illness of two years' duration. I believe that the second patient is making rapid progress.

5. Finally, it is suggested that to decide definitely on the value of this form of therapy it might be well to establish some central office where all the data could be conveniently assembled and compared. Since most institutions are prepared to carry out only a few of these time and energy consuming treatments at any one time and since there is such a wide diversity of opinion as to the point at which a patient may be considered to have gained a "remission," such uniform statistics would be of incomparable value.

### MEDICOLEGAL ABSTRACTS

**Venereal Diseases: Physical Examination of Suspected Rapist.**—The accused was charged with the crime of rape committed on a young girl under the age of 12 years. The girl developed gonorrhea after the alleged rape and while the accused was in jail under arrest for the crime a physician, accompanied by two or three policemen, went to the jail and subjected him to an examination to determine whether he had gonorrhea. The physician was permitted to testify that the examination disclosed that the accused was infected with gonorrhea. A conviction followed and the accused appealed to the Court of Appeals of Kentucky.

The examination, the accused contended, was made over his protest and against his will and consent. The physician, however, and others present at the time of examination testified that the accused consented to it and made no protest whatsoever. There was no evidence, the court said, to show that any force or duress was resorted to by the physician or others present to induce the accused to submit to the examination, or that he was otherwise intimidated. In the absence of such a showing, if the accused willingly submitted to the examination and offered no protest or objection to it, the evidence obtained thereby was competent; otherwise it would be incompetent. The mere fact that the officers were present was insufficient, in the opinion of the court, to raise the presumption of duress. But whether the examination of the accused's person was made with or without his consent should have been submitted to the jury under appropriate instructions. The trial court should have instructed the jury in substance that, if they believed from the evidence that the examination of the accused's person was made against his will and without his consent, the evidence obtained thereby was illegal and incompetent; but if made with his consent or without objection by him, it was competent for their consideration. The failure of the trial court so to instruct the jury constituted a prejudicial error. For that error, in addition to others, the Court of Appeals reversed the judgment of conviction and remanded the case.—*McManus v. Commonwealth (Ky.)*, 94 S. W. (2d) 609.

**Compensation of Physicians: Liability for Medical Services Allegedly Rendered by Physician to His Brother.**—The plaintiff, a physician, brought suit against his brother's widow to recover the reasonable value of services he allegedly rendered to his brother. Between May 1, 1926, and Oct. 10, 1934, the plaintiff contended, he rendered professional services to his brother for which he had not been reimbursed. He made no demand on his brother for payment during the latter's lifetime because of a promise by the brother to name the plaintiff as legatee in his will. The brother, however, left his estate to his widow. The trial court held that part of the amount claimed was barred by the three year statute of limitations but rendered judgment for the plaintiff in the amount of \$500. The defendant appealed to the court of appeal of Louisiana, second circuit.

In Louisiana, said the court, parol evidence is inadmissible to prove any liability on the part of a deceased person "if a suit upon the asserted indebtedness or liability shall have been brought within a delay of twelve (12) months after the death of the deceased," unless the evidence consists of the testimony of at least one credible witness, besides the plaintiff, or unless it be corroborated by a written acknowledgment or promise to pay signed by the debtor. The record in this case disclosed that the plaintiff's brother died in the latter part of 1934 and that suit was filed in February, 1935, or within "a delay of twelve months" after the death. The only proof tending to establish the asserted indebtedness was that given orally by the plaintiff. The court felt impelled, therefore, to hold that the plaintiff's suit failed because of noncompliance with the requirements of the Louisiana law with respect to proof.

Furthermore, the court said, although the plaintiff testified generally that he attended and administered to his brother as

a practicing physician and that he expected and was entitled to compensation for the services which he gave, his own testimony regarding many of the details of his visits and the claimed medical acts performed not only did not benefit his cause but was injurious to it. Opposed to the testimony of the plaintiff that he actually rendered medical attention was that of several other reputable witnesses. The decedent was a patient in a sanatorium for several months in 1932 and for a similar period in 1934. A large part of the plaintiff's total claim was for alleged services rendered during these two periods. The testimony of the physician who operated the sanatorium, that of the decedent's regular family physician, and that of two nurses who attended him was to the effect that the plaintiff visited his brother in the capacity of a relative and not as an attending physician. During these stays in the sanatorium, the decedent was solely under the care and supervision of other physicians. Furthermore, the court said, the record contained uncontradicted testimony that it is not the common practice in the medical profession for a physician to make a charge for services rendered to his brother or to other members of his immediate family. In view of these facts, the court thought that the judgment of the trial court for the plaintiff was manifestly erroneous. The judgment was reversed and the plaintiff's suit dismissed.—*Longino v. Longino (La.)*, 169 So. 186.

**Pneumoconiosis: Liability of Employer at Common Law.**—The plaintiff contracted pneumoconiosis during the course of his employment with the Libby-Owens-Ford Glass Company and instituted suit at common law to recover damages. The company interposed a general motion to dismiss the action, contending that the complaint failed to charge it with having violated any statute of Illinois and that in the absence of a statute the company was not liable to the plaintiff for any disability due to an occupational disease. The trial court sustained the motion to dismiss, the appellate court affirmed the judgment of the trial court, and the cause was brought before the Supreme Court of Illinois by appeal on a certificate of importance.

It is a long established rule of common law origin, said the Supreme Court, that an employer must furnish his employee a reasonably safe place in which to work. An examination of the cases in Illinois and at common law which support this rule discloses that it is based on decisions involving accidental injuries rather than occupational diseases. Reflection, continued the court, makes it apparent that this must be so because occupational diseases were unknown to the common law. The weakness of the argument on behalf of the employee, said the court, lies in its failure to distinguish between a "safe" and a "healthful" or "sanitary" place in which to work. At common law no duty devolved on employers to furnish a healthful or sanitary place of work for employees. The judgment of the appellate court for the defendant was therefore affirmed.—*McCreery v. Libby-Owens-Ford Glass Co. (Ill.)*, 2 N. E. (2d) 290.

**Medical Practice Acts: Sale of Nostrums.**—Posey was convicted of practicing medicine without having registered in the office of the district clerk. He appealed to the court of criminal appeals of Texas.

The medical practice act of Texas declares that a person shall be regarded as practicing medicine (1) who publicly professes to be a physician and treats or offers to treat any disease, disorder, physical deformity or injury; or (2) who treats or offers to treat any disease, disorder, physical deformity or injury for compensation. A witness testified that he went to Posey and complained of boils on his neck and aches and pains in his body. Posey told the witness that he thought that his medicine would do him good and sold him a quart of medicine or tea. Subsequently, the witness made a return visit and purchased a second quart of the tea. On another occasion the witness had a carbuncle on his neck and he went to Posey, who told him that he had some salve that might do it good. A box of the salve was purchased by the witness. On still another occasion the witness called on Posey and told him that he had some pains in his knees and Posey sold him a bottle of liniment, expressing the opinion that the liniment

Dr. Robert H. H. H. H.

1935

place. Of three cases of oral tears in the lower half of the globe, two have been operative successes and one, after an immediate success, recurred. In two cases of moderate myopia the lower half of the retina was detached, but no retinal hole was found. Katholysis was employed in an attempt to pin down the retina immediately behind the ora serrata and just in front of and behind the equator by two lines of punctures in these respective planes passing between the lower borders of the internal and external rectus muscles. There was immediate success, but one recurred one month and the other two months after operation. In the upper half of the globe the sealing of extensive rents and large horseshoe-shaped tears has not been effective. Katholysis alone is insufficient to effect firm and reliable union between the choroid and retina around large tears situated in the upper half of the globe and should be augmented by surgical diathermy. Recently it has been the author's practice in such cases to make a number of punctures with the kathode over the site of the hole and to circumvallate its edges with two or three rows of punctures set 0.5 mm. apart and, outside this, to apply two or three rings of Larsson's surface diathermy, the points of contact on the sclera being placed 2 mm. apart. The results have been successful in three cases of large upper temporal horseshoe rents and in two cases of multiple round holes treated by this modification.

**Chronic Meningitis in Weil's Disease.**—Murgatroyd describes a case of Weil's disease associated with a progressive type of chronic meningitis, in which the first evidence of meningitis was observed four months from the beginning of Weil's disease. *Leptospira* was recovered from the cerebrospinal fluid six months and from the urine of the patient eight months after the onset of the illness. No sign of meningitis was recorded during the early typical stage of the disease, which was accompanied by jaundice. Although the patient had apparently had an attack of visceral Weil's disease in December 1935 and was still infected months later, his serum and cerebrospinal fluid possessed practically no agglutinating power against the infecting organism and against various other strains of *Leptospira*. The diagnosis was made by demonstrating the organism in the cerebrospinal fluid and urine by guinea-pig inoculation. Until an antileptospiral serum was administered, the illness was apparently steadily progressive. Since Weil's disease may occur without jaundice, it should be considered in any obscure case of meningitis. Indeed, since Weil's disease may fail to present any specific syndrome, its possibility should be borne in mind in any case of obscure pyrexia.

**Ultraviolet Irradiation in Treatment of Varicose Ulcers and Eczema.**—When Eidinow took charge of the light department of the St. John Clinic four years ago, ninety-two patients suffering from varicose ulcer and varicose eczema had been attending once or twice a week for more than three years. Although they had regularly received local treatment with ultraviolet rays emitted from the tungsten arc, their lesions did not heal. The technic of treatment was changed and after three months sixty-six of these patients were completely healed and discharged cured. The technic adopted included: (1) exposure of the ulcer and the skin area from 1 to 1½ inches surrounding the edge of the ulcer to massive doses, equivalent to six erythema doses of rays, emitted from the quartz air-cooled mercury vapor lamp and (2) application of adhesive elastic bandages. The result of such treatment has been consistently successful. The exposure to ultraviolet rays of wavelength shorter than 3,000 angstrom units sterilizes the surface of the ulcerated area and augments the circulation; this promotes the healing and makes the surface wound inoffensive and free from unpleasant odor. The lamp is placed at a distance of 12 inches for ten minutes. A vacuum type of quartz air-cooled mercury vapor lamp, consuming 2.5 amperes and 105 volts between the electrodes, is employed. This is equivalent to five times the erythema dose of the normal white skin.

Immediately after exposure the tissue paper protecting the rest of the leg is removed and an elastic adhesive bandage is tightly applied from the base of the toes, over the foot including the heel, and up the leg to the knee. The patient is instructed to keep the bandage clean but not to interfere with it in any way. It is kept on for one week, when the patient again reports. The bandage is then removed, the skin is cleansed with acetone and the treatment is repeated. Week by week the ulcer area becomes smaller until healing ultimately occurs. The cases of varicose veins selected for such therapy were those in which the health of the patient or the enormous size of the veins did not permit treatment by injection of sclerosing solutions or by ligature. Treatment was applied twice a week for eight weeks. In varicose eczema the technic is similar to that applied in the treatment of varicose ulceration. There is an intensive exposure to ultraviolet rays, equivalent to six normal skin erythema doses, to localized patches of eczema, and the normal skin for half an inch surrounding each zone is also irradiated. An elastic adhesive bandage is then applied to the whole foot and leg and left undisturbed for one week. The ultraviolet irradiation causes an active inflammatory reaction, followed by edema, blistering, and finally exfoliation of the skin. Bandaging the limb with adhesive strapping and thus keeping the treated lesion covered gives relief to the patient, as the painful symptoms following intensive ultraviolet irradiation are thereby diminished. Healing of the skin gradually takes place, and week by week steady improvement may be recorded. The treatment is repeated once a week for from six to eight weeks; by this time healing is well advanced. During the last five years more than 240 cases of varicose ulcers have been treated, 90 per cent of which have been healed within six months. Patients are asked to report afterward for examination every two months for intervals as long as from one to two years.

**Treatment of Scabies with Benzyl Benzoate Lotion.**—With the help of the hospital dispenser, Kissmeyer improved the formula of the benzyl benzoate lotion used by Ludwig Nielsen and simplified the method of treatment so that it could be carried out in forty-five minutes without causing any damage to the skin. Since January 1933 some 8,000 cases of scabies have been treated in which it has proved practically ideal. The treatment is an ambulatory one; only children of less than 1 year of age should be treated in the hospital. It seldom gives rise to any dermatitis or irritation of the skin, and even cases of scabies pyogenically infected and very young children can be treated without any serious after-effects. The formula consists of equal parts of soft soap (British Pharmacopeia 1932), isopropyl alcohol and benzyl benzoate. The quantity necessary for each patient is about 150 Gm. The patient anoints the whole body with soft soap, rubbed with special care into those parts commonly attacked by the acarus. He then soaks in a warm bath, at 100 F., for ten minutes, rubbing himself during the bath. While wet the body is brushed all over with the lotion for five minutes with a brush of Russian pig bristle, special attention being paid to the affected parts. The patient then rests, allowing the body to dry, and then continues the brushing for a further five minutes, after which the body is dried gently and the patient resumes the clothes worn before the treatment was started. Twenty-four hours later a second bath is taken and clean clothes are put on. Underclothes are not disinfected but only washed and, if possible, boiled. Bedclothes should be boiled or otherwise sterilized. All members of a family or household should be treated on the same day, even though they may not show any signs of scabies.

would relieve the pains. According to this witness, Posey made no physical examination of him, did not diagnose his condition, and did not write for him a prescription. Posey did not, according to the evidence, publicly profess to be a physician or surgeon. If we understand the testimony in this case, said the court of criminal appeals, it wholly fails to show that Posey charged, directly or indirectly, for any treatment of any disease, disorder, physical deformity or injury. If it be a violation of the law, the court said, for a person to go to another and ask for his recommendation or opinion as to what medicine might be of benefit to him, if used, it is quite likely that the proprietors of practically every drug store in the state of Texas could be held to be practitioners of medicine because of their recommendations to people who come to them for medicine for supposed ailments claimed by the would-be purchaser. Expressing the opinion that the testimony in the case failed to support the conviction, the court of appeals reversed the judgment of the trial court and remanded the case.—*Posey v. State (Texas)*, 94 S. W. (2d) 451.

**Harrison Narcotic Act: Sufficiency of Indictment Against Physician.**—Dr. H. A. Glatzmayer was convicted of violating the Harrison narcotic act under an indictment charging him with having dispensed narcotics as a registered physician not in pursuance of written order forms and "not in the course of his professional practice." The physician appealed to the United States circuit court of appeals, fifth circuit, contending that the indictment was insufficient because it did not allege that the person prescribed for was not a patient.

The Harrison narcotic act, said the court, makes it a crime to sell narcotics except in pursuance of a written order on a prescribed form. The act provides, however, that nothing in it shall apply to the dispensing or distribution of any of the narcotics mentioned in it to a patient by a physician in the course of his professional practice only. The indictment might have charged simply the dispensing of narcotics not on order forms, ignoring the fact that the accused was a physician, thus leaving to him to prove his immunity. The indictment alleged, however, that the accused was a registered physician and in order to state a case the indictment had to go further and negative the physician's privilege. This it effectively did by alleging that the prescriptions were not issued in the course of his professional practice. A patient is a sufferer under treatment by a physician. If the physician is acting in the course of his professional practice, necessarily he has a patient. Conceivably, a physician may have a patient under treatment and might dispense to him drugs not to alleviate his condition but to gratify his craving for them, as he might in like manner dispense to a person not a patient. To sustain the physician's privilege there must be a patient and a dispensing in the course of professional practice. The words "not in the course of his professional practice" as used in the indictment, said the court, constitute an allegation that the dispensing by the physician was not done as a physician. The indictment, in the opinion of the court, was sufficient to state an offense. The judgment was affirmed.—*Glatzmayer v. United States*, 84 F. (2d) 192.

**Basic Science Act: Referendum Measure Improperly Submitted to Voters.**—The Arizona legislature in 1933 enacted a law providing that all applicants for licenses to practice the healing art must, before being permitted to take examinations to test their fitness to practice, demonstrate their proficiency in the sciences of anatomy, physiology, pathology, chemistry, bacteriology and hygiene by passing an examination conducted by a nonsectarian, impartial board of examiners. Thereafter a referendum petition on this law was filed in the office of the secretary of state. The Arizona constitution provides that referendum measures shall be submitted to the voters at the "next regular general election" following the filing of the petition. A vacancy having occurred in the office of Representative of Arizona to the Congress, the governor of the state called a special election to fill the vacancy. It was at this election that the referendum measure was submitted and approved by the people.

In the present proceedings, one St. Louis Estes was convicted of practicing the healing art without having obtained a certificate from the state board of examiners in the basic

sciences. He appealed to the Supreme Court of Arizona, contending that there was no law in the state requiring that he obtain a basic science certificate in order to practice the healing art. With this contention the Supreme Court agreed. The referendum measure, said the court, was improperly submitted to the voters and consequently it did not become a law. The constitution required that the measure be submitted at the next "general" election. It was erroneously submitted at a "special" election. The judgment of conviction was reversed and the cause remanded with directions to dismiss the charge.—*Estes v. State (Ariz.)*, 58 P. (2d) 753.

Systematic Appendectomy in Surgical Treatment of Acute Appendicitis. Djémil Pacha.—p. 1449.

**Thyroidectomy for Decompensated Cardiopathies.**—Santy and Bérard, basing their work on the fact that in myxedema the circulatory flow is slowed down without any peripheral signs of heart failure, tried to supply an artificial equilibrium between an insufficient heart and the vital needs of the organism by lowering the basal metabolism. In their four cases the technic was more or less the following: Incision under local anesthesia so that all muscles of the neck, including the hyoid, were conserved intact, except the pretracheal muscles. Access over the right lobe of the thyroid body, which is dissected from above downward. Ligation of the branches of the superior thyroid artery with fine silk thread in the capsule, which is gradually detached from the thyroid body, while every small vessel is ligated. One should try to remain between the capsule and the parenchyma. Below is noticed the inferior parathyroid, which is pushed back behind the capsule. The left side is approached in the same manner. No recurrent nerve is seen here. The first patient shows continued cardiac improvement. The intense dyspnea is lessened. She can get up and about. She shows no sign of thyroid insufficiency; her metabolism is not below normal. The second patient lived about a year following the operation and it seems that the thyroidectomy at least did not harm her. In the third patient, one month after the thyroidectomy, there was a more regular rhythm of the heart, the edemas subsided and the dyspnea was less pronounced. The fourth case proved a complete failure, probably because of endocardiac lesions. Of twenty-one patients operated on by other authors, fifteen died inside of eighteen months. There were one success and three improvements. It is likely that the indications were not correct. However, an ideal indication is unusual. It is therefore certain that surgical therapy is still a hazardous procedure in decompensated heart diseases.

\*Practical Importance of Examining Reticulocytes in Peripheral Blood for Clinical Study of Pulmonary Tuberculosis. M. Szour and C. Bergenbaum.—p. 79.

**Malignant Abdominal Lymphogranulomatosis.**—Bacaloglu and Enachesco state that Paltauf and Sternberg occupy an important place in the work on reticulo-endotheliosis, or Hodgkin's disease. This disease shows itself under all kinds of forms, general and local, and assails one organ or a group of organs. Its gravity is high and its prognosis always fatal. Its origin is obscure and it belongs to the inflammatory neoplasms of an unknown virus. It is a mistake to think of Hodgkin's disease as a tuberculous disease. In tuberculosis of longer standing one often sees a lymphogranuloma developing side by side with tuberculous lesions. In the same manner one sometimes sees an epithelial cancer imposing itself on the wall of a tuberculous cavity. The blood picture is quite variable. It supplies no absolute indication for a diagnosis or even for a prognosis. Many authors insist on the frequency of monocytosis characterized by sudden and capricious appearance and disappearance. This is particularly true in the forms in which enlargement of the spleen is associated with prurigo. Leukopenia predominates in abdominal forms. The lesions are first seen in the abdominal and later also in the peripheral lymph nodes. An important symptom is the undulating fever with an acme lasting about seven days. The abdominal form of Hodgkin's disease is most rarely recognized during life. The absence of peripheral lymph nodes and the impossibility of a biopsy confuse it with other febrile disturbances. The undulating fever together with the gastro-intestinal symptoms,

notably diarrhea alternating with short periods of constipation, and the number of red corpuscles falling to about 3,000,000, are indications of abdominal lymphogranulomatosis. The spleen is considerably enlarged. The leukocytes are diminished and show a predominance of polymorphonuclear neutrophils and absence or diminution of polymorphonuclear eosinophils. On establishing these symptoms one may resort to the only means of prolonging the life of the patient: roentgen therapy.

**Examination of Reticulocytes of Peripheral Blood for Study of Pulmonary Tuberculosis.**—Szour and Bergenbaum call attention to the clinical value of reticulocytes. The erythroblastic system of the bone marrow reacts to a bacillary infection in a specific manner and is characteristic for the given allergic state of the person. Repeated reticulocyte examinations in the same patient illustrate the play of immunobiologic forces of the patient. The authors used the staining method of Levaditi and Ehrlich. On examining tuberculous patients every fifteenth day they found that whenever the process was stationary there were likewise no changes in the reticulocytes. In subacute cases there is a rise of from 6 to 12 per thousand of erythrocytes. In acute cases they may go up to 60 or 70 per thousand, with younger forms predominating. In florid cases and also in caseous pneumonia there may be as many as 100 per thousand of red blood corpuscles. Briefly, whenever the process is more acute the number of reticulocytes is increased, with younger forms predominating. But in advanced stages their number again falls to about from 2 to 10 per thousand. It follows that the increase of reticulocytes depends largely on the strength of the defense forces of the organism. It manifests the struggle of the organism in the erythroblastic center of the bone marrow. Return to normal is a sign of cure or of considerable remission. When there is an improvement in the general condition but no improvement in the reticulocytes there is only an apparent remission. A rapid fall in reticulocytes without change in the general condition is a grave prognostic omen.

**Benzotherapy in Pulmonary Suppurations.**—In a previous article Goldkorn reported some of his results from intravenous injections of sodium benzoate in pulmonary abscesses. He injected 2 Gm. or 10 cc. of a 20 per cent solution from five to ten times, obtaining drainage and a benign influence on expectoration. In more abundant cases it was necessary to increase the dose to 3 or 4 Gm., and he has injected from 4 to 8 Gm. twice daily when the condition was alarming. Of twenty-two cases of pulmonary abscess there were five of a septic form with rapid destruction of tissue, fifteen had a duration of more than six weeks, and two were fatal. A permanent cure was obtained in eighteen patients who were under observation for three years. In six cases of gangrene the therapeutic effect was remarkable in from five to six days. The antiputrid action of sodium benzoate in doses of from 8 to 16 Gm. made the unpleasant breath disappear completely. In four recent cases the cure was permanent. One case of six months' duration was much improved and one was fatal. In 30 per cent of the patients there were dizziness and flashes before the eyes, which lasted but a minute. For this reason it is good to proceed slowly with the injection. In three cases of pulmonary abscess there was pain in the abdomen, which lasted four minutes after the injection. A few drops of tincture of opium or belladonna relieved the symptoms. Small doses of sodium benzoate were also given in bronchopneumonias. There were no contraindications.

## Current Medical Literature

### AMERICAN

The Association Library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (\*) are abstracted below.

**Importance of Statistics in Cancer Campaign.**—According to Cramer the experimental investigation of carcinogenesis has revealed two different and largely independent aspects of the etiology of cancer: the proximate cause of cancer—the intimate cellular changes that take place when a normal cell becomes malignant—and the remote causes of cancer—the factors and conditions capable of bringing about this intimate cellular change. Cancer mortality statistics are not likely to give information on the proximate cause of cancer, but they are the most valuable and almost the only material available for the study of the remote causes of cancer in man. Occupational cancer is an example in which remote causes of cancer have been identified from an analysis of statistical data. This form of cancer has thus become preventable. Further analysis of the cancer mortality according to exposed sites and nonexposed sites has shown that in the exposed sites the incidence of cancer rapidly increases as one descends in the social scale. This proves that the bulk of the total cancer mortality can be avoided and is being avoided by the upper social classes and that therefore a large fraction of the total cancer incidence is preventable. There is, in fact, "social cancer" as there is "occupational cancer." A method of obtaining information from statistical data concerning the remote causes of cancer is by a comparison of the cancer mortality statistics from different countries, provided they are comparable. Cancer as a disease is not inherited; only the susceptibility to a development of cancer in response to persistent carcinogenic stimuli can be inherited. In man the etiologic significance of this factor, apart from certain rare conditions, is not sufficiently important to condemn the offspring of a cancerous ancestry to the probability of the development of cancer. But from the point of view of the diagnostician a history of cancer in the family of a patient in which the diagnosis is doubtful, with the possibility of malignant disease, should be considered a factor weighing in favor of a diagnosis of cancer. Cancer mortality statistics, if reliably collected and suitably analyzed

with the necessary statistical corrections, represent a method for identifying some of the remote causes of cancer in man for some of the organs that take the heaviest share in the total cancer mortality; a method, in other words, to make a considerable part of cancer a preventable disease.

**Isolation of Pure Strains of Cells from Human Tumors.**—Pinkus describes pure strains of cells isolated from three human tumors and carried for from three to nine months. During this period, gradual changes of the properties of the strains took place. The working hypotheses and suggestions offered for further investigation are: 1. Those tumors which because of their clinical importance were the most common objects of former students, i. e., the squamous-cell carcinomas, are probably least suitable for tissue culture. 2. Rapidly growing tumors forming dense areas in vitro offer the best chance of success. 3. Spontaneous malignant growths are composed of a genetically inhomogeneous and labile cell material. 4. Inhomogeneity and lability differentiate spontaneous tumors from transplantable malignant growths, the elements of which have been thoroughly stabilized by selection. 5. Inhomogeneity and lability account for a great part of the difficulties encountered in the cultivation of human tumors. 6. Careful selection of specimens and a technic taking into account points 3, 4 and 5 will probably make possible permanent cultivation of pure strains of human malignant cells.

**Thrombocytosis Produced by the "Fat-Soluble T Factor."**—Schiff and Hirschberger found it possible to produce with regularity an increase in the number of platelets in normal children. The unknown factor responsible for the increase in the platelet count is not vitamin A but is present in sesame oil and absent from cod liver oil and olive oil. Additional proof of this fact is that vitamin A when dissolved in olive oil instead of in sesame oil has absolutely no effect on the thrombocyte count. This platelet-increasing factor is effective even in small doses: from 8 to 10 drops of sesame oil a day was sufficient to bring about a notable increase in the platelet count. It is possible that the reason for this was the existence of a new fat-soluble vitamin. For the time being the authors wish to designate this substance as the "fat-soluble T factor." Ultraviolet irradiation seems to destroy the factor.

**Changes in Growing Skeleton After Administration of Bismuth.**—Caffey has selected four types of lesion to illustrate the bismuth changes that follow syphilitic therapy: (1) the lesion which occurs directly after a single course of treatment, (2) that which occurs many weeks after a single course, (3) that which occurs after multiple courses during several years and (4) that which occurs in the new-born whose mothers received bismuth during pregnancy. Observations have revealed shadows in the skeletal roentgenograms of such patients similar to "lead lines" in lead poisoning. Analogous x-ray changes were produced in growing dogs by the administration of bismuth. The histologic features of the bismuth lesion in the

- Important Factors in Roentgenotherapy. O. David.—p. 120.

**Irrigation in Gonorrheal Vulvovaginitis.**—Häberlin states that in the dermatologic clinic of Zurich gonorrheal vulvovaginitis in children has been treated during the last two years by continuous irrigations with solution of acriflavine hydrochloride, the concentration of which is gradually increased from 1:6,000 to 1:2,000. A Nélaton catheter, which is connected with an irrigator, is introduced into the vagina. The catheter is fastened to the thigh. The backflow of the irrigation fluid escapes through an opening in the mattress. The treatment does not bother the children, since they can be in a half-sitting position and entertain themselves with toys. The irrigation is given for about three hours in the morning. The drop velocity is 40 per minute. In the morning and evening the rectum and the urethra either are irrigated with a silver preparation or suppositories are introduced. In addition to this, the children are given sitz baths with potassium permanganate in the morning and in the evening. This procedure is continued for four weeks. If at the end of this period the examination for gonococci gives negative results, the treatment is continued for another four weeks under constant bacteriologic control. Then the provocative methods are applied. In case of relapse, the entire cycle is repeated. Of the thirteen children in whom this treatment was employed, twelve remained free from relapse during observation periods of from two to fifteen months. In one child a relapse occurred after four months, and a reinfection by the mother seemed possible in this case. The author emphasizes that this method of treatment not only reduces the time required for the treatment to about half of the length formerly required but is also more effective.

- Gangrene of Penis from Actinomyces: Case. D. Pampari.—p. 357.

**Alcoholization of Third Branch of Trigeminal Nerve.**—Oppezzi describes a technic for alcoholization of the third branch of the trigeminal nerve in the treatment of neuralgia. The injection is made with a long and thin needle having a cork disk running along its shaft. The patient is asked to open the mouth slightly and the needle is introduced just below the midpoint of the zygomatic arch 4 or 5 cm. until the needle point touches the pterygoid process. Without the needle being moved, the disk on its shaft is moved until it touches the skin. The needle is then withdrawn a few millimeters and directed forward so as to form an angle of 30 degrees with an imaginary line perpendicular to the cutaneous plane pierced by the needle and pushed in again until the disk touches the skin. The disk is then pulled away from the skin a few millimeters and the needle is pushed in farther until the disk again touches the skin. At this point the patient complains of pain which irradiates to the teeth and the tongue, indicating that the needle has reached the mandibular nerve near its exit from the foramen ovale. Now 1 cc. of alcohol is injected. In exceptional cases the needle point meets a bone surface which prevents its reaching the foramen ovale, regardless of the different angles at which the needle is directed. The author found by anatomic studies of the region that the obstacle is usually due to calcification of Hyrtl's crotaphic buccinator ligament but may also be due to calcification of Civinini's pterygospinous ligament abnormally placed. De Froe and Vagenaar point out the calcification of Hyrtl's crotaphic ligament. They

denied, however, that Civinini's pterygospinous ligament, abnormally developed and calcified, may be the obstacle. The author states that calcification of either or both ligaments may be the obstacle.

- Chronic Appendicitis: Diagnosis and Treatment. M. Mauro.—p. 1118.

**Sodium Benzoate in Tuberculous Cough.**—Quaranta reports the results obtained by administering sodium benzoate for cough in pulmonary tuberculosis. The treatment consists in a daily intravenous injection of 5 cc. of a 25 per cent sodium benzoate solution for fifteen consecutive days and can be repeated at intervals of ten days. The tolerance of the patient is tested before the treatment by a daily intravenous injection of 1 cc. of the 25 per cent solution of sodium benzoate for two consecutive days. The author's dose is usually well tolerated. During administration of the treatment the patient is on a regular diet and is given the medicinal treatment indicated, such as lecithin, balsams, arsenicals and analeptics. Sodium benzoate changes the nature of the sputum. It has an anti-septic action on bacteria associated with tubercle bacilli in the sputum and inhibits the action of the vagal sympathetic nervous ends that control bronchial secretion. The quantity and quality of the sputum are favorably modified, the attacks of coughing diminish in number and frequency and the general condition of the patient improves. In the majority of cases, satisfactory results are evident after seven or eight injections. The number of failures is about 6 per cent. These results were obtained by the author in a large number of cases.

**Cholesterol Tuberculous Pleurisy.**—According to De Almeida Prado, cholesterol pleurisy originates in chronic fibrous tuberculosis of long duration (twenty, thirty or forty years). The fluid is formed in the pleural cavity and pushed by adhesions, which form during the course of the disease, until it is encysted between a part of the pleura on one side and the adhesions on the other. Originally the fluid is abundant in leukocytes, lymphocytes and cholesterol. As it becomes encysted it passes through certain changes of the cells and fatty substances and is transformed into a sterile fluid of chyliform nature and milky appearance, which contains formed cholesterol. The fluid may be encysted at any part of the pleura. The most frequent locations are the axillary region and the posterior inferior part of the pleura. The disease evolves slowly without disturbing the patient's general condition. Fever, cough and pain are caused by tuberculosis but not by the effusion. Dyspnea is a frequent symptom. The thorax is retracted on the side of the effusion. The signs given by auscultation and percussion correspond to the condition of the lung. The prognosis depends on the evolution of tuberculosis. Operation on the pleuritic bag should be avoided whenever possible, because of the tendency of the condition to the formation of a fistula after performance of an operation. In the literature, regional thoracoplasty is advised as the operation of choice. A case is reported by the author.

**Alkali Reserve in Barbituric Anesthesia.**—Unti and de Moraes studied the variations of the alkali reserve produced by the sodium salt of *n*-methyl-cyclo-hexenyl-methyl barbituric acid, intramuscularly, amytal and the sodium salt of isopropyl-bromalyl-*n*-methyl-malonylurea anesthesia. In one of the cases in which amytal was administered the anesthesia was completed with tutocain spinal anesthesia, and in the other three cases

skeleton are described, and chemical analyses of the bismuth, calcium and phosphorus content of the bismuth zone are given. The effect of parathyroid extract on the formation of the bismuth lesion and the differences between the skeletal changes following treatment with arsenical preparations and with bismuth compounds are discussed.

**Hydatid (Echinococcus) Disease in Canada and the United States.**—Magath reviews the past trend of the disease in Canada and the United States and states that at least 482 cases of hydatid disease have been recorded in Canada and the United States since the first case was seen in 1808. Ten new cases diagnosed at the Mayo Clinic are added to the cases already reported. All of 95 per cent of the cases in which the nationality of the patient is known have occurred among immigrants, and four cases have been reported in which the patients were natives born in the United States but who probably acquired the infection in foreign countries. Three persons most likely acquired the infection in Canada and nineteen in the United States. Infection among men is more frequently seen in Canada and the United States than among women, and children (only twelve cases) are but rarely infected. The organs most commonly involved are the same as those in countries in which the disease is endemic. Foreign patients have come chiefly from the countries in which hydatid disease is relatively common and from which relatively many immigrants have come. Iceland, Italy, Germany, Greece, Russia and Great Britain account for 75 per cent of the cases. Evidence points to a falling incidence of the disease, as it affects man, in Canada and the United States, and among human beings the curve of incidence flattened out about 1924. Some evidence indicates that the incidence among hogs is increasing. Apparently the usual life history between dog and sheep is not typical in Canada and the United States and this probably explains the almost complete absence of hydatid disease among native human beings. So rarely does a native citizen of Canada or the United States who has never left his country have hydatid disease that such an event will occur less often than once in about five years; this is stated on the basis of past experience.

**Comparison of Tests on Blood Serologic Reaction.**—Tate and Robards tabulated the serologic examinations of 2,159 individuals. This included all patients as they were admitted

to the East Louisiana State Hospital over a period of three years. The blood serologic reaction was tabulated on 110 syphilitic individuals by the Kolmer-Wassermann, Kahn and Johns precipitation tests. These patients had received from two to eight weeks of antisyphilitic therapy, and comparisons of the Kolmer-Wassermann, Kahn and Johns precipitation tests were made on bloods from 130 constitutional syphilitic individuals, after extensive treatment had been given. Tabulations and comparisons of the Kolmer-Wassermann, Kahn and Johns precipitation tests were also made on 160 cerebrospinal syphilitic individuals after extensive antisyphilitic treatment. The authors' conclusion is that the first few antisyphilitic treatments given to a syphilitic individual cause a negative or doubtful reaction sooner by the two precipitation methods than by the Kolmer-Wassermann reaction. But, as the course of treatment is continued, the precipitation tests return to positive and under rigid treatment stay positive longer than the Kolmer-Wassermann reaction. No syphilologist or laboratory technician should rely on a single test for the diagnosis or prognosis of syphilis.

**Salpingostomy and Tubal Implantation for Treatment of Sterility.**—Greenhill's review of the literature concerning salpingostomy and tubal implantation for the purpose of overcoming sterility presents an unfavorable attitude toward these operations. The chief reasons for this are the relatively few live babies secured by these measures, the disproportionately high number of ectopic pregnancies that have resulted, and other complications that may follow such operations. Of the 107 replies received to questionnaires sent to members of the American Gynecological Society and the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, sixty were definitely opposed to salpingostomies and tubal implantations for the purpose of overcoming sterility, about one fifth were distinctly in favor of such plastic operations, one seventh felt that the operations were worth while occasionally, and the remainder did not express any opinion concerning the usefulness of these operations. An analysis of about 818 plastic operations reported in the questionnaires revealed that fifty-four pregnancies took place after these operations; however, only thirty-six live babies were delivered. Ten of the fifty-four pregnancies ended in abortion and eight were ectopic pregnancies. Careful selection of cases and improved technic in performing these plastic operations on the tubes will most likely yield a larger incidence of live children for those who feel inclined to perform these operations. There is certainly much more justification for doing them when the abdomen is opened for some specific

amytal was administered alone. The alkali reserve, two hours after administration of the derivative of barbituric acid, diminished in seven cases, increased slightly in two and remained unchanged in one case. Acidosis was not reached in any of the cases. In five cases the determination of the alkali reserve was repeated twenty-four hours after administration of the barbituric acid derivative. In two of three cases with decreased alkali reserve the latter rose in twenty-four hours. In the other cases the alkali reserve decreased still more. In one case in which the alkali reserve did not change in two hours and in one case in which it rose in two hours it decreased in twenty-four. According to the author, vomiting and nervous excitation of the patient after the anesthesia depend on nervous and humoral disturbances rather than on the variations of the alkali reserve. Postoperative acetoneuria does not necessarily coexist with the presence of acidosis. In the five cases in which amytal was given, the alkali reserve was normal before administration of the anesthetic. Two hours later it decreased in four cases and increased in one. Amytal administered alone may produce a decrease in the alkali reserve which is in proportion to the decrease of the pulse and of the movements of respiration. The sodium salt of isopropyl- $\beta$ -bromalyl- $\alpha$ -methyl-malonyleurea produced a marked decrease of the alkali reserve in all cases during the first six hours. In one of the cases the alkali reserve increased and in the other decreased still more in twenty-four hours.

**Periosteal Lipoma.**—Dujovich and Shraer say that periosteal lipoma is rare, usually congenital and of uncertain etiology and pathogenesis. The volume and weight of the tumor depend on its age. On palpation the tumor gives a characteristic sensation of softness similar to that of a bag of wool. The shape and number of lobules of the tumor vary. Macroscopically, section of the tumor shows that it is yellow and made up of fat lobules. It contains connective fibrous tissue, which in some cases exists in abundance (fibrolipoma) and then it cuts like fat bacon. In other cases it has a gelatinous appearance. Microscopic examination reveals that it is composed of fat cells and connective fibrous tissue. The tumor may suffer myxomatous degeneration (myxolipoma). Periosteal lipoma does not cause cutaneous ulceration or suppuration. Cases in which the center of the tumor becomes calcified have been reported in the literature. Usually periosteal lipoma originates in the periosteum with one or more pedicles without involving the bone (true periosteal lipoma). In some cases the tumor penetrates the bone and partially infiltrates it (osteoperiosteal lipoma). Intra-osseous lipoma is exceedingly rare. Periosteal lipoma may develop on any bone, the long bones, the cranium and the vertebrae being the most frequent locations. As a rule it does not become adherent to the skin, joints, vessels or nerves. The tumor adheres to the deep tissural layers and forms adhesions with the muscles, which make its removal difficult. The differential diagnosis depends on the location of the tumor. In the cranium it has to be differentiated from encephalocele in children and from dermoid cysts and syphilitic gumma in adults. When it is located in a vertebra it has to be differentiated according to its location from cervical lymph nodes, branchioma, cysts, angioma, diffuse symmetrical lipomatosis of the neck, meningocoele and atypical Pott's disease. When the tumor is located at the long bones it has to be differentiated from simple superficial lipoma, hydatid cyst of the muscles, syphilitic gumma and sarcoma. Usually the tumor follows a slow and progressive course of development, except in atypical cases in which it develops rapidly and disturbs the general condition of the patient. The treatment consists in complete removal of the tumor and of the pedicle and in scraping of the bone at the site of origin. If the lipoma originates in an exostosis, the latter has to be resected. The authors report

two cases of periosteal lipoma on a rib and on the humerus, respectively, in patients aged 60 and 50 years. Both patients recovered after removal of the tumor.

**New Maneuver in Pulmonary Diseases.**—The maneuver described by Catuogno is as follows: The patient is placed in a vertical position, either standing upright or sitting in bed. The inferior border of pulmonary resonance is outlined by light percussion. The patient is then bent forward at a right or obtuse angle (if he is standing) or at an acute angle (if he is sitting at the edge of the bed) and percussion is repeated. The border of pulmonary resonance will then be displaced downward 4 or 5 cm. in a normal thorax and 1 or 2 cm. in pulmonary emphysema. There is no displacement if adhesions are present, and displacement upward if there is pleurisy. The downward displacement of pulmonary resonance in the normal thorax is due to a change in position of the lung toward the costodiaphragmatic sinus. Lack of displacement indicates inability of the lung to move because of adhesions. The displacement of resonance upward is caused by displacement of the fluid from the costodiaphragmatic sinus, for that is the point of less resistance to intrapleural pressure induced, during the maneuver, by the postural change of the thorax.

Clinical Significance of Electrocardiography in Cardiac Infarct. J. Freundlich.—p. 622.

**Zinc Vapor Intoxications.**—Chrometzka observed zinc vapor intoxications in a large number of workers who did zinc welding. Of the general symptoms, emaciation is the most noticeable, but fatigue, headaches and nervous symptoms are also frequent complaints. The most characteristic symptoms are those of the mucous membranes. Not only is the nasal mucous membrane irritated, but there is also tracheitis, laryngitis and bronchitis. The gastric mucosa is also severely affected. The patients complain of gastric pressure, loss of appetite, nausea and vomiting and, in severe cases, cramplike pains in the epigastrium and occasionally sour eructation. Even the mucous membranes of the urinary passages show signs of inflammation. In view of the fact that even the mucous membranes which do not come in contact with the zinc vapors are inflamed, the author suggests that the process is an exudative inflammation. The changes in the blood are not uniform. The increase in reticulocytes observed in many cases is apparently not caused by an impairment of the blood forming organs but rather by way of the gastric changes. The author thinks that in selecting workers for zinc welding attention should be paid to the constitution and particularly the sympathetic nervous system. Moreover, zinc welders should receive adequate amounts of fat and milk; their work period should be comparatively short, and they should be given an opportunity to change their work periodically.

**Insensible Perspiration in Dropsical Disorders.**—Kestermann and Schleining point out that there are contradictions in the literature on insensible perspiration. Some authors assert that there may be a "negative" insensible perspiration, that is, an increase in the body weight, in spite of an excess of the egesta over the ingesta, while others deny such a possibility. In view of the fact that "negative" insensible perspiration was observed by several investigators in patients with cardiac decompensation, the authors decided to study this problem on patients with heart disease. First they made tests on ten patients with chronic congestion of the liver, edemas and continuous increase of the body weight. The tests were made in the morning, while the patients were still fasting, and with a scale that had an exactness of 0.1 Gm. Of a second group of patients who were subjected to the test, the majority had heart disease while one had syphilitic cirrhosis of the liver and another nephrosis and ascites. The authors were never able to detect a "negative" insensible perspiration; that is, an increase

indication than there is for performing the laparotomy solely for the purpose of operating on the tubes to correct sterility.

**Nonirritating Opaque Medium for Uterosalphingography.**—Titus and his co-workers state that the source of chemical salpingitis and parametritis frequently initiated by injections of iodized oil for uterosalphingography seems to lie in the liberation of free iodine from the oil. Skiodan in watery solution is entirely nonirritating and has been used extensively in urologic work, but its lack of viscosity made it unsuitable for uterosalphingography. Several different combinations with viscid mediums were devised in an effort to develop a solution of the same viscosity as iodized oil. A solution containing 40 per cent of skiodan in 20 per cent acacia finally proved suitable. Injections in the tubes of rabbits showed no irritative, histologic changes, and its clinical use has followed thus far with entirely satisfactory results. Moreover, the roentgenograms seem sharper and clearer than with the iodized oil preparations.

**Elimination of Intestinal Gas Shadows in Roentgenography.**—Kenning and Lofstrom used pitressin as an aid in eliminating gas shadows, which, on a roentgenogram, cause confusion and error. This work includes observations of more than 1,000 patients. Repeated doses increase the tone of the intestine without ill effect. In their experience no harmful after-effects have been observed. Its use is indicated in any case in which gas shadows obscure observations on the roentgenogram. Some of the uses specifically are in cholecystography, examinations of the kidney, ureter and bladder to reveal the presence of stones, tumors, perinephric abscess, and the like, intravenous urography, retrograde urography and examinations of the lumbar spine and pelvis. Extreme care should be exercised in the use of pitressin in cases of cardiac decompensation associated with marked hypertension, coronary sclerosis and thrombosis, and acute, complete mechanical intestinal obstruction of long standing. Pregnancy has not proved to be a contraindication, at least through the sixth month. The optimal effect in eliminating gas was obtained approximately from thirty to forty-five minutes following injection. It has also been noted that gas shadows reappear in from two to three hours. The night before examination a cleansing enema is given. This is followed in the morning, about one and one-half hours before the time set for roentgenography, by another enema. One hour before, 0.5 cc. of pitressin is given intramuscularly. This is repeated in half an hour. In some few cases of peritonitis and traumatic ileus as many as six ampules (0.5 cc. each) have been given to produce satisfactory roentgenograms. However, in most cases, two injections of 0.5 cc. each were found to give the desired results. The authors do not mean to imply that

there will be no evidence of gas within the intestine; however, it is minimized to such an extent that the roentgenograms are clearer and much more diagnostic than those obtained by any other method. The hepatic flexure of the colon is shortened, being drawn down away from the gallbladder area, thus eliminating shadows due to superimposed intestine. The cost of the medication is amply compensated for by the saving in time, reexamination and the greater ease in diagnosis when better quality films are available.

**Giant Cell Tumors of Bone.**—In summarizing their experience on a material of forty cases (fifteen giant cell tumors, twenty-five osteitis fibrosa), Freund and Meffert state despite several factors which they have in common that localized osteitis fibrosa (solid or cystic form) has to be considered different from giant cell tumor, at least clinically. Giant cell tumors are more prevalent in the second and third decades of life, and localized osteitis fibrosa in the first and early part of the second decades of life. Giant cell tumor localizes mainly in the lower epiphyses of the radius and femur, while osteitis fibrosa localizes in the upper metaphyses and diaphyses of the humerus, femur and tibia. Giant cell tumors are slowly progressive with a tendency to break through the periosteum and to invade the surrounding soft tissue, frequent recurrence following operation. The cause is relatively benign in osteitis fibrosa, especially for the cystic form, with some cases of spontaneous healing and, as a rule, good response to surgery. Therefore age, localization and the clinical course are factors that make it doubtful whether localized osteitis fibrosa and giant cell tumor represent only different manifestations of the same nosologic entity. As far as the treatment is concerned, careful and thorough curettage in localized lesions followed by implantation of a good number of bone chips seems to be the method of choice. Roentgen treatment may be of advantage. In more extensive giant cell tumors with soft tissue involvement, amputation has to be considered as the quickest way to permanent cure if roentgen treatment or less radical surgical means fail to improve the condition.

**Sodium Bismuthate Soluble for Administration in Syphilis.**—Hanzlik and his associates have developed a new preparation of sodium bismuthate, sodium bismuthate soluble in solution and in dosage form, for intramuscular and oral administrations in the treatment of syphilis. The essential composition of the solution for injection is 3 per cent sodium bismuthate, 8 per cent triisopropanolamine, 50 per cent propylene glycol and the remainder water. The composition for oral administration is essentially the same, except that there is less propylene glycol and no water. The single dose proposed for intramuscular injection is 1 cc. and for oral administration 6.7 cc. of solution or 0.2 Gm. of sodium bismuthate in capsules. Intramuscularly, sodium bismuthate soluble is well tolerated in animals and patients, is promptly, rapidly and completely absorbed, is excreted in the urine and is distributed throughout

in weight. The patients with heart disease lost approximately 0.5 Gm. a minute, that is, 30 Gm. an hour, a value slightly below that of healthy persons. The authors conclude that an insensible gain in weight as the result of autochthonous water formation in the organism, owing to the transformation of oxygen deficient substances into those with a higher oxygen content, has not been demonstrated as yet.

- \*Experimental Contribution to Explanation of Mechanism of Postoperative Hypochloremia. E. Michałowski and I. Vogelfanger.—p. 78.

**Action of Insulin Injected into Portal Vein.**—With the aid of angiostomy, Steigerwaldt and Kürten investigated in rabbits the action of insulin that has been injected into the portal vein. They were able to show that the action of this insulin compared to that of insulin injected into the vein of the ear increased as the glycogen content of the liver decreased. The experiments prove that the counter regulation to the insulin action can be elicited by the humoral way and that the liver passage of insulin is only a regulatory process.

**Determination of Pressure in Pulmonary Artery.**—According to David and Siedek, the pressure in the pulmonary artery is the most important factor in the pulmonary circulation. Since a surgical determination of this pressure as done in animals is not feasible in human subjects, it is understandable that the pressure of this artery was not measured. The observation that, during tracheoscopy or bronchoscopy, heart-synchronous movements can be seen approximately 1 cm. below the bifurcation, induced the authors to register these oscillations because, in view of the topographic relations between the pulmonary artery and the right bronchus, these movements on the bronchial wall could be regarded as transmitted pulsations. They developed a technic that employed a rubber balloon and a differential capsule for the registration of the oscillations. The method was first tried on dogs and its reliability was tested by the surgical determination of the pressure. Then the nonsurgical method was used on human subjects and it proved possible to register pharmacodynamic changes in the pulmonary circulation.

**Mechanism of Postoperative Hypochloremia.**—Michałowski and Vogelfanger maintain that the postoperative humoral-chemical changes have a causal connection with the surgical trauma and, from this point of view, they consider the pathogenesis of postoperative hyperazotemia and hypochloremia. Hyperazotemia and hypochloremia form a syndrome which has been designated as hypochloremic hyperazotemia. The authors point out that the decomposition products of the proteins in the surgical wound which enter the blood stream exert a histamine-like action. They regard these histamine-like substances as the first cause in the pathogenesis of the postoperative disturbances. In order to gain further insight into the action of these histamine-like substances, they made experiments on dogs. First they studied the effect of the intracutaneous injection of histamine and then the action of its intraperitoneal injection. In the summary they say that they regard the hypochloremia in the blood as the result of the intraperitoneal formation of exudate and they think that the same mechanism is responsible for the development of postoperative hypochloremia. Its degree is determined on the one hand by the quantity of the toxic and histamine-like substances and on the other hand by the local vascular conditions. It is the more severe, the greater and more vascularized is the exposed surface. The experiments furnish further support for the assumption that substances with histamine action play a part in postoperative hypochloremia.

- Panmyelophthisis and Agranulocytosis. C. H. Behr.—p. 423.

**Gonotoxic Icterus.**—Popper and Wiedmann direct attention to the fact that jaundice is comparatively frequent in the course of gonorrhea. It is the result of a parenchymal impairment of the liver. This report is based on observations in sixty-one cases. The incidence of hepatic impairment in patients with gonorrhea (thirty-seven in 1,000 cases) makes a connection probable. The clinical aspects of this hepatic disorder are like those of catarrhal icterus, moderate or mild cases of long duration being in the majority. The authors also describe cases of acute yellow atrophy of the liver with fatal termination, which developed in the course of gonorrhea. Whether acriflavine hydrochloride plays a part in the development of hepatic impairment could not be determined. The authors think that at the most it is a supporting factor. The treatment with gonococcus vaccine seems to increase the susceptibility for a hepatic impairment. Moreover, the vaccine therapy may elicit the signs of a serous inflammation. The hepatic impairment develops, as a rule, only in prolonged and complicated gonorrhea, presumably caused by gonotoxins, but contributory factors, such as alimentary intoxications, may play a part in the individual cases.

**Secretion of Saliva.**—Fabian reports studies on the salivary secretion of patients with gastric carcinoma, pernicious anemia and histamine refractory gastric achylia. Tabular reports of the results of his studies indicate that the quantity of saliva is reduced in all three forms of achylia. The lowest values were detected in pernicious anemia; that is, in patients in whom the gastric mucosa is most severely impaired. Although these studies indicate a connection between the secretory action of the gastric and salivary glands, the connecting causal factors are not understood as yet, because the salivary glands are also subject to various nervous regulations, such as sympathetic-parasympathetic influences, subcortical mechanisms and central nervous factors. At any rate the observation that a deficient gastric secretion is always accompanied by a reduction in the salivary secretion indicates that the functional condition of the gastric glands is at least a contributing factor. In studies on the rhodan content of the saliva the author found that it is most severely impaired in patients in whom the achylia is caused by carcinoma. In this connection he points out that the literature reports a reduced rhodan content of the saliva in various disorders that lead to cachexia. The chloride content of the saliva is only slightly influenced by the deficient gastric secretion and the ferment content not at all. The author thinks that the latter factor does not contradict a connection between gastric and salivary secretions but only suggests that the salivary secretion is influenced also by other factors.

- Roentgen Diagnosis of Diseases of Gallbladder. E. Zdansky.—p. 133.

**Roentgen Irradiation in Blood Diseases.**—Sgalitzer points out that in 1927 Teschendorf introduced total irradiation with roentgen rays into the treatment of leukemia and that shortly thereafter he himself decided to try it in polycythemia rubra. In the course of nine years he resorted to total irra-

the body, including the central nervous system; it exists in the body in the electronegative state. The characteristic behavior is that of a soluble product of anionic bismuth. Orally or gastrically, sodium bismuthate is definitely absorbed in animals and human subjects, as indicated by fatal and toxic doses in animals, absorption from ligated intestine in animals, urinary excretion in animals and human beings and general bodily distribution in animals. Most of the bismuth is expelled with the feces, but a part may be retained in the body, possibly in the intestinal wall. Intramuscular injections of sodium bismuthate soluble are definitely effective in experimental syphilis and in early and late clinical syphilis. The gastric administration also appears to be effective in early and late clinical syphilis. Both intramuscular and gastric administrations of sodium bismuthate soluble have been free from objectionable side actions. The margins of safety for therapeutic administration are ample. Bismuthate soluble offers possibilities of determining the value of prophylactic oral treatment for syphilis.

**Kahn and Kolmer-Wassermann Reactions in Bejel.**—Hudson states that between Feb. 8 and June 21, 1935, identical serums from 200 individuals having bejel were examined by two laboratories. Neither laboratory was acquainted with the clinical history of the case at the time of reading. Of the 200 cases, 139 (69.5 per cent) had positive reactions in one or more of the three serologic tests. The Deir-ez-Zor laboratory reported the Kahn reaction positive in 61.5 per cent, and the Beirut laboratory in 58.5 per cent; the Kolmer-Wassermann reaction was positive in 42.5 per cent, with 11.5 per cent anti-complementary. The Kahn reactions of the two laboratories agreed relatively and absolutely in 83 per cent of the series of 200 cases. The two Kahn reactions and the Kolmer-Wassermann reaction agreed relatively and absolutely in 68 per cent of the 200 cases. The complement fixation reaction is less sensitive in bejel than the precipitation reaction and has the further disadvantage of giving anticomplementary reactions.

**Fate of Deeply Implanted Dermal Grafts.**—Peer and Paddock found that the dermal graft, when taken from the skin of the abdomen as a free autograft and inserted beneath the skin of the chest, remained in place and fused with the surrounding connective tissue. In the majority of sections, in spite of attempted complete removal of the epidermis, some epidermis remained. This remaining epidermis formed closed cyst cavities of microscopic size, containing horny material and fragments of hairs. In the later sections (seven months and one year) horny material was seen in the cavities of microscopic size surrounded by granulation tissue without epithelial lining. Sebaceous glands were observed only in the implants

of one week's duration. Hair follicles were observed only in the implants buried up to three weeks, inclusive. Sweat glands were seen in all sections, but in later sections they were in the process of degeneration and fibrous replacement. Granulation tissue surrounding the implant was of the chronic inflammatory type containing lymphocytes, macrophages, epithelioid cells and often giant cells, in some cases with the formation of granulomatous nodules. In the granulomatous tissue surrounding the implant, at times within the implant, bodies were observed within the giant cells and nodules. These bodies resembled hairs and fragments of hairs.

**Friedman Test and Pituitary Tumor.**—McCullagh and Cuyler performed the Friedman test in a selected group of 946 nonpregnant individuals and observed 209 positive reactions. Endocrine disease was suspected in each case. In 131 cases in the group, a clinical diagnosis of pituitary disease was made and excessive amounts of urinary gonadotropic substance by means of the test were found in fifty-nine of these cases. Among the cases diagnosed as pituitary disease there were fifteen of pituitary tumor. Of the eight cases of pituitary neoplasm in which positive Friedman test results were found, the diagnosis was verified in four—by necropsy in three and at operation in one. In two cases the clinical evidence of tumor was clear. In two cases in which the evidence indicating the presence of pituitary tumor was less striking there was outspoken clinical acromegaly and enlargement of the sella turcica, although there was no distinct bony erosion of the sellar boundaries and no visual field changes. In the seven cases of pituitary tumor in which negative Friedman reactions were obtained the diagnosis of tumor was verified in four, at

diation in forty-four cases of polycythemia, forty-two of which responded well. He applies the roentgen rays from a distance of 1.5 meters, so that the entire body is exposed to the cone of rays. The tension is from 180 to 200 kilovolts. The individual irradiations last fifteen minutes. They are applied on six successive days, alternately to the ventral and dorsal side of the body. The blood is examined one week after the completion of these first six irradiations. The number of leukocytes and not that of erythrocytes is of chief interest in this blood test. The behavior of the leukocytes varies greatly in the different patients, for, whereas their number is hardly changed in some, it may have dropped in others from 10,000 to 7,000. In all patients with polycythemia in whom the leukocytes prove to be sensitive to roentgen rays, great precaution is necessary in the total irradiations, which must be distributed over a rather long period. The total number of treatments varies between twelve and twenty-two. If in the course of the first six irradiations the leukocytes have shown resistance to the rays, the total number of irradiations can be given in about four weeks. In case of ray sensitivity, however, the treatments have to be distributed over eight or ten weeks. After the treatment of the polycythemia has been completed, that is, after the number of erythrocytes has been normalized, the patients should be subjected to control tests of the blood at intervals of two or three months, in order to detect recurrences. The author observed relapses after eighteen months and even after five years. Total irradiation alone is often effective in the first two years of myeloid leukemia, whereas in the later stages it should be combined with local irradiations of the spleen. In lymphatic leukemia the total irradiation should be combined from the beginning with local irradiations of the spleen and lymph nodes. With this treatment the course of the leukemia is usually somewhat milder, but the final outcome is not influenced by the total roentgen irradiation.

**Cobra Toxin in Neurologic Disturbances.**—In view of the fact that cobra toxin contains neurotoxins, Brünner-Ornstein decided to investigate the analgesic action of cobra toxin in painful neurologic conditions. She tried it in cases of trigeminal neuralgia that had proved refractory to medicinal and physical therapeutic methods. She uses a preparation standardized in mouse units. The injection is made intracutaneously, near the painful site. Immediately after the injection there may be a slight increase in pain, which after about thirty minutes is followed by a noticeable reduction in pain. In several cases the hypalgesia extended far beyond the painful zone. Injurious effects in the form of hemorrhages, infiltrates or necroses were never observed. In a few cases, in which larger doses had been administered, slight pigmentations were observed, which disappeared again in the course of a few weeks. The author employed the cobra toxin in the treatment of fourteen cases of severe trigeminal neuralgia. Six of them have been free from pain for the last three or four months, four are greatly improved, two are still receiving treatment and, in the two remaining cases there was no noticeable improvement. The author intends to continue the studies and try the cobra toxin in various neuralgias and neuritides.

Typhoid (Large Cities) As Social Disease. A. Ławrynowicz.—p. 72.

**Prolonged Respiration of Carbon Dioxide.**—Tomaszewski and his co-workers have made experiments on three persons with the object of verifying the changes produced in the constitution by daily inhalation for one hour of large quantities of 8 per cent of carbon dioxide. Their results showed decided changes in the blood and respiratory tract as a consequence of the inhalation of 1.5 liters of carbon dioxide in one minute. The changes may be divided into immediate and late effects. The direct changes produced in the blood of veins and in the respiratory tract consist of increase in the level of carbon dioxide, slight increase in the oxygen capacity, decrease

in the saturation of oxyhemoglobin of the respiratory tract, increase in the ventilation of the lungs, increase in the depth and speed of the respiration, increase in the percentage of carbon dioxide in the air vesicles, increase in the percentage of carbon dioxide in the expired air, slight increase in the metabolism, initial quickening and then slowing of the pulse, and tendency to slight increase in the blood pressure. The late changes appearing after several days consist of increase and then decrease of the level of carbon dioxide in the blood of the veins, distinct increase in the oxygen capacity of the blood, better saturation of oxyhemoglobin in the venous blood, increase in the quantity of red blood corpuscles and in the amount of hemoglobin, and marked increase in the capacity of the active lungs.

\*Treatment of Ulcers of Leg, Especially with Insulin Ointment. K. Hedén.—p. 235.

\*Contribution to Statistics on Pulmonary Emboli. G. Hultquist.—p. 264.

**Treatment of Ulcers of Leg.**—Hedén says that, while the Schlasberg lead-vinegar plaster does not always give such excellent results as in the twelve cases he reports, the method has perhaps been the best heretofore for treatment of varicose ulcers of the leg. Since 1934 he has more and more extensively used insulin in ointment and he reports the results of this treatment in sixty-six cases. Seventeen of the patients were men and forty-nine were women and their ages ranged from 25 to 80 years. In the first nineteen cases, dextrose tolerance tests were not made; in forty-seven they were given. Complete healing occurred in forty-one (62 per cent), almost complete healing in two (3 per cent), improvement in eleven (17 per cent) and no change in twelve (18 per cent). In the large majority of cases, disturbance in the glycoregulation was found. Although there is no reason to suppose that age itself plays a part in the glycoregulation, still the older the person the greater is the chance that there have been infections or toxic injuries that might affect the glycoregulation. The preponderance of women suggests that an endocrine factor related to sex is present in disposition to ulcers of the leg. Diabetic, hepatic and toxic types of glycoregulatory disorder were found among the cases in which healing followed after use of insulin ointment. Of the seventeen patients under 50, only the three with the toxic type of glycoregulatory disturbance resisted the treatment. The treatment was successful in all the cases of diabetic type. No certain type of glycoregulatory disturbance could be established as pathognomonic for the refractory cases.

**Pulmonary Emboli.**—In a necropsy material of 814 cases from St. Erik's Hospital from 1925 to 1934, with pulmonary embolism assigned as the immediate cause of death in 153 cases and pulmonary embolism together with other disturbances in seventy-nine, Hultquist finds that women are more disposed than men to emboli in the pulmonary artery, the difference being especially marked in fatal embolism. The disposition to embolism increases with age. The danger of fatal embolism is greater in stout persons than in those with average or poor nutrition; adiposity apparently does not favor the occurrence of small emboli or of thrombus formation. Circulatory disturbances promote the appearance of emboli, and the slowing up of the blood stream depends not only on diseases of the heart and of the blood vessels but also on impairment of the circulation due to surgical interventions, particularly in the abdomen. Malignant tumors and pulmonary tuberculosis do not promote embolism. The frequency of pulmonary embolism was almost twice as great in cases from the internal division as from the surgical, explained partly by the greater disposition in the former to embolism (higher age, greater number of circulatory disorders and so on). The frequency of fatal embolism was about the same in the two divisions. The author found no evidence that intravenous injections are in the great majority of cases of significance for the occurrence of embolism and thrombosis. No relation was noted between embolus mobilization and weather conditions. The fluctuations in monthly frequency, with minimums in May and September and maximums in April, August and October, are ascribed to monthly variations in the composition of the patient material, the frequency of other disturbances, and so on.

necropsy in one and by operation in three. In the first two cases there was a questionable excess of gonadotropic substance but, since the reactions were not positive, these are included in the group. In the remaining cases the Friedman tests gave completely negative results. In cases of pituitary tumor in which the Friedman test reaction is positive, roentgen therapy to the pituitary may be followed by marked diminution in the excretion of gonadotropic substance as judged by the test; in two instances this has been accompanied by a diminution in the excretion of testicular hormone.

**New Phase of Intestinal Allergy.**—While going over his records of rectal prolapse in infants and children, Ehrlich was impressed by the fact that this condition often occurred in allergic families and that the patients had allergic symptoms at the time of the examination or developed them later. He tested allergically some of the patients whose personal or family histories presented symptoms of allergy. The results tend to show that in many cases of intestinal disturbance the real cause may be determined by the allergic method of testing. Tests were made for every article of diet that ten children ate or could receive from their mother's milk. There was rectal prolapse in five cases, rectal relaxation in three and loose bowel movements in two. Purgation was produced in six cases by including in the diet foods giving positive skin reactions. Although allergic treatment is not a panacea in the treatment of rectal prolapse and rectal relaxation, a careful study of each individual case and the application of the knowledge so gained may be rewarded with a success commensurate with the efforts put forth. All cases of rectal prolapse and rectal relaxation may not be allergic, but cases with positive allergic histories are. Rectal prolapse and rectal relaxation are the severest types of allergic enteritis, with the former a more severe degree of the latter condition. Allergic methods of treatment will no doubt decrease infant mortality in intestinal disorders.

### Etiology of Coronary Thrombosis and Angina Pectoris.

—In the opinion of the Jacksons, many acute attacks now diagnosed as coronary thrombosis (which may or may not be present) are really due to pulmonary embolism (or pulmonary thrombosis). They believe that usually juices liberated from tissues injured during anginal attacks, vomiting and straining cause the intravascular clotting resulting in dyspnea, cyanosis and circulatory and blood coagulating disturbances. The lungs serve as a filter for the general circulation and are more liable to collect emboli than are the coronary arteries. The nature of the pain developed in angina pectoris and coronary thrombosis, the nerves involved and the information revealed by surgical, pharmacologic or physiologic investigation of these mechanisms are discussed. There is no clinical or physiologic evidence to indicate that a pain-producing spasm of the coronary arteries ever occurs.

**Physiologic Action of Diethylene Glycol.**—Haag prepared two identical blends of tobaccos with the exception of the hygroscopic agent employed. Sample A contained 2.75 per cent of diethylene glycol, as verified by analysis; sample B, 3 per cent of glycerin. As evidence of the degree of irritation provoked, the objection of the animal and the blepharospasm, as well as the extent and duration of the hyperemia and edema of the conjunctiva, were tabulated at regular intervals of several minutes. There was no significant difference as to either intensity or duration in the irritation produced by the instillation into the rabbit eye of the two smoke solutions studied. For toxicity studies, smoke solutions were prepared from the two types of cigarettes by gravity extraction over water. The finished solutions contained the same amount of nicotine, namely, 0.66 mg. per cubic centimeter, and the toxicity of these solu-

## RELATION OF AMERICAN MEDICAL ASSOCIATION TO CERTIFICA- TION OF SPECIALISTS

CHARLES GORDON HEYD, M.D.  
President of the American Medical Association  
NEW YORK

Many years ago I was impressed on reading the *Wealth of Nations* by Adam Smith. In chapter I, on the causes of improvement in the productive power of labor, he takes as his example the division of labor in the trade of the pin maker. By repetitive action skill is acquired, technic developed and a tremendous increase in production obtained. Specialism increases productivity, enhances accuracy and skill, economizes time and labor and inherently promotes ingenuity and discovery. In the acquisition of medical knowledge in our country we passed through the preceptor period and then the closing of the inferior medical schools through the labors of the Council on Medical Education and Hospitals of the American Medical Association. A little later a standard premedical education was required and the opportunities for postgraduate instruction were greatly increased.

Specialism in medicine has always existed, modified by environment, superstition, religion and the state of medical knowledge. In ancient times among the peripatetic disciples of Aesculapius there were physicians who confined their practice to a definite category of disease. Special medical societies and special hospitals were established in consonance with the existing level of medical knowledge. The Royal Ophthalmic Hospital was founded in London in 1804, the Royal Hospital for Diseases of the Chest in 1814. In New York City in 1825 a fever hospital was established, and the Lying-In Hospital in Boston was founded in 1830.

With the development of the microscope, clinical thermometer and stethoscope (1819), the vaginal speculum (1849), the ophthalmoscope (1851), the laryngoscope (1855), Lister's antiseptic surgery, Kussmaul's stomach tube (1867), the cystoscope (1879), the roentgen ray (1895), the bronchoscope (1898) and the respiratory calorimeter (1904) the age of discovery enlarged the possibilities of diagnostic precision by instrumentation. This advance in medical knowledge necessitated intensive training and specialized technical aptitude. In short, the advance in the physical sciences supplied medicine with a host of instruments of precision.

Specialism, however, cannot be a thing apart from the field of medicine and must fit into the general

pattern of medical services. Primarily, the growth of specialism both individually and collectively must rest on a broad foundation of general medical training. The assumption of specialistic training by any practitioner of medicine without first being willing to submit his credentials as to his special training is incompatible with his responsibility to society. The technical qualification of the specialist may be determined by examinations, tests of ability, competence of experience and hospital training. These tests can be made and the results appraised and passed on only by men of special training and experience. From its inception the American Medical Association has been concerned with medical education and it could not fail to take cognizance of the rising tide of criticisms against the so-called self-anointed specialists, pseudospecialists and the masquerading specialists.

It has long been evident that the public, as well as the profession, demanded some means of identifying the adequately trained specialist. In New Jersey a bill was introduced into the legislature providing that the state should pass on the qualifications of those claimed to be specialists. New York State was entertaining similar proposals.

It was the opinion of the members of the Council on Medical Education and Hospitals of the American Medical Association that it would be disastrous for the states to assume the function of designating qualified specialists. First, it was apparent that specialistic standards should be uniform throughout the country and that confusion and probable divergent requirements of the various states should be avoided at all costs. Since the national government could not undertake this work, it seemed to be necessary that voluntary agencies be created to function extralegally but with the force of public opinion, as does the Council on Medical Education and Hospitals itself. Secondly, it was realized that while a populous state like New York might conceivably set up some machinery for identifying specialists, it would be wholly impossible in many of the states to find a group of highly trained specialists capable of conducting the necessary examinations. Thirdly, it was realized that if the states should undertake the certification of specialists, the procedure would necessarily be subject to political influence and, since no one of the states has as yet been able to create a satisfactory system of testing the applicants for the general medical license, it seemed to be absurd for them to attempt the far more difficult task of conducting examinations for each of the specialties.

For these reasons the House of Delegates at the Milwaukee session (1933) authorized the Council to approve of such special boards as should meet the standards which the Council itself should formulate. By this means it was hoped that properly organized

tions, after the addition of enough sodium chloride to make them isotonic, was established on white mice by intraperitoneal injection. These smoke solutions were slightly more toxic than their nicotine content indicated but were found to have the same toxicity on white mice by intraperitoneal injection.

**Differential Diagnosis of Poliomyelitis.**—From 1927 to 1935 inclusive, 790 patients were admitted to the Herman Kiefer Hospital with the diagnosis of poliomyelitis. The initial diagnosis was confirmed in 445 of these, or 56.3 per cent. In the first or systemic phase, poliomyelitis differs in no important essential from the onset of the average acute general infection. Top and Brosius believe that it is far better to err in this manner than to have omitted consideration of the disease, and physicians are to be commended for being alert to the possibility of poliomyelitis. In general, certain clinical observations discount the importance of the consideration of poliomyelitis as the diagnosis in a suspected case. They are irrationality or coma, marked temperature elevation, convulsions, meningismus, severe pain or swelling of affected extremities, cervical lymphadenitis, abdominal tenderness and a prolonged illness with subsequent paralysis. In spite of careful attempts to avoid pitfalls in the diagnosis of poliomyelitis, an occasional bizarre condition presents itself which is provocative of a diagnosis wide of the mark. Such a case was seen during the month of July, when cases of poliomyelitis normally begin to be reported. The history of onset, the observations on physical examination and the subsequent clinical course of the illness drew the authors' attention sharply to the consideration of poliomyelitis as the diagnosis in this instance. With the exception of the appearance of xanthochromatic spinal fluid, the history of a fall and sensory paralysis the condition did

not appear to give sufficient weight to call into question the credence of a diagnosis of poliomyelitis, but with subsequent paralysis the patient came to necropsy with this clinical diagnosis. One member of the clinical staff disagreed with the diagnosis of poliomyelitis, although entertaining no definite idea with respect to the pathologic picture. At necropsy a diagnosis of diffuse sarcomatosis of the spinal leptomeninges was made.

**Management of Ureteral Stones.**—After trying the technique suggested by McKay in a few cases with indifferent success, it occurred to Moore that the filiform bougie might be used to better advantage by passing the filiform and carrying the threads well beyond the stone, even as far as the renal pelvis, and then withdrawing by traction on the filiform only, with no effort to induce bowing. The obstructing stone causes the threads to wad above it, forming a small mass which does not easily permit the point of attachment of the threads to be withdrawn unless the stone is brought along also. If a calculus is engaged in this way and does not slip out easily by steady or intermittent traction, the bougie may be inserted further and the strands of thread may be easily drawn out along with the filiform. The ureter should be dilated before insertion of the dislodger. A direct cystoscope of the Braasch type is preferred, as the catheter guide of this instrument renders unnecessary the passage of the bougie through a length of catheter, as advised by McKay; also there is no deflector to become entangled with the threads. Of thirty-one patients, in whom there were thirty-three ureteral stones to be removed, twenty-four stones were removed on the cystoscopic table; twelve at the first treatment, seven at the second, four at the third and one at the fourth, making a total of forty-two, or an average of 1.75 treatments for each stone. This type of treatment has been limited to stones of less than 1 cm. in diameter in the lower half of the ureter. After removal of a stone, one or two number 5 F. ureteral catheters are left in place for from twenty-four to forty-eight hours, on the assumption that the ureteral orifice might become completely occluded from edema, predisposing to acute infection.

boards should be created in the major medical specialties and that the operation of these various boards would be conducted on a high standard of professional integrity and proficiency. Standards formulated by the Council, in collaboration with the Advisory Board for Medical Specialties, were ratified by the House of Delegates and have since then been accepted by all the boards. In the composition of these boards, representatives were chosen by one or more national societies in each specialty and also by the corresponding section of the Scientific Assembly of the American Medical Association.

We have thus created a system which provides for a thorough technical examination by a group of men selected by the specialists themselves. This examination is national in scope and uniform for all sections of the country. It is free from the domination of partisan politics, which would be unavoidable if certification were under state control. The educational standards and examination procedure of these boards are under the supervision of the Council on Medical Education and Hospitals and therefore also under the control of the House of Delegates of the American Medical Association. In this manner we have safeguarded the rights of all those who are qualified to be known as practitioners in the special fields of medicine.

It is extremely important that the special boards should have some guide as to the quality of the training of the candidates for examination. For each one of the dozen boards to conduct a survey of the opportunities offered in each of the 400 hospitals which offer residencies in the specialties would be manifestly impossible. The Council is therefore planning to undertake a more thorough study of these residency hospitals in order that more adequate information regarding their educational opportunities may be placed at the disposal of the special boards.

Some one has said that a journey always begins with the first step, and the appearance of the American Medical Association in the plan for certification of specialists was inevitable when in 1907 the American Medical Association began classifying medical schools, together with the results of the state board examination of candidates for the license to practice medicine. The Advisory Board for Medical Specialties was organized in 1933-1934 for the certification of medical specialists in the United States and Canada. This board cooperates with the Council on Medical Education and Hospitals of the American Medical Association and is composed of representatives of:

- The American Board of Ophthalmology.
- The American Board of Otolaryngology.
- The American Board of Obstetrics and Gynecology.
- The American Board of Dermatology and Syphilology.
- The American Board of Pediatrics.
- The American Board of Psychiatry and Neurology.
- The American Board of Orthopaedic Surgery.
- The American Board of Urology.
- The American Board of Pathology.
- The American Board of Surgery.
- The American Board of Internal Medicine.
- The American Board of Radiology.
- The Association of American Medical Colleges.
- The American Hospital Association.
- The Federation of State Medical Boards of the United States.
- The National Board of Medical Examiners.

The various boards in their respective and autonomous capacity certify the applicants.

The degree of competence for the removal of an appendix or for an ophthalmologic examination of the

eye should be the same in California or Honolulu as in New York, and progress would have been inhibited, if not canceled, by any legislative action, entailing as it does possibilities of political contamination, favoritism and personal bias.

A broad plan of certification embraces two phases: (a) certification as to the competence of the applicant and (b) searching out and listing of facilities to increase the opportunities for specialistic training. The latter obligation cannot be carried out by the separate boards but must of necessity be performed by the Council on Medical Education and Hospitals. Furthermore, the latter aspect of activity implies an adequate education of the public as to what is essential for certification of a specialist and cooperation with the hospitals, the various boards of regents, and the state and national boards of medical examiners.

State medical societies cannot assume the leadership in this problem. Their function is more special and their geographic influence confined to their boundaries. The American Medical Association represents all the states. It is a federation with all the scientific points of view. It has been intimate with and created that public opinion which has made for changes in medical education, in equipment and building of medical schools, in the classification of medical schools, in the classification and listing of hospitals for interns and residents. Therefore it is most preeminently fitted to enter into the most intimate relationship with the various boards of certification.

A great statesman once defined public office as a public trust, and that thought may be paraphrased by stating that specialism is a public trust and its devotees must and should be certified by men of special training and that this must be within the framework of a nationally constituted society; to wit, the American Medical Association.

In a far larger sense, however, in the background of all certification is a pedagogic fact that knowledge consists in instruction and education. An effective teacher may provide competent instruction, but education depends on the capacity of the individual to utilize that instruction. In the final analysis, specialism will rest on the applicant's character. To that end the qualification of candidates is all important. There shall be general qualifications embracing satisfactory moral and ethical standing in the profession: membership in the American Medical Association or, by courtesy, membership in such Canadian or other medical societies as are recognized for this purpose by the Council on Medical Education and Hospitals of the American Medical Association.

More than 70 per cent of our medical school graduates are looking forward to limiting their practice to a specialty. One half of these will probably limit themselves to a special field of medical endeavor without having had any experience in general practice. To develop scientific effectiveness and clinical knowledge, certain special training is essential. In brief, the Council and the Advisory Board for Medical Specialties consider that an applicant desiring to be certified as a specialist shall have had: (1) a period of study after the internship of not less than three years in clinics, dispensaries, hospitals or laboratories recognized by the same council as competent to provide a satisfactory training in the special field of study; (2) this period of specialized preparation to include intensive graduate training in anatomy, physiology, pathology and other basic medical sciences which are necessary to the proper

**Venereal Disease Control.**—After a fairly thorough study of the epidemiologic aspect of the problem of venereal disease control, Lubowe contends that it must be approached from four major angles: through (1) the practical education of the general public; (2) the establishment of well equipped clinics under jurisdiction of the city department of health and manned by capable and experienced physicians who are specialists in the field, and excellently trained public health nurses and social service workers endowed with the natural gifts of personality and sympathetic understanding of human nature and behavior; (3) the achievement of a proper relationship between the clinic and the private physician; (4) the control of the antagonistic and the uncooperative patient. If home conditions, which at the present time in many cases are deplorable and lend themselves to accessible and uncontrolled sexual contact, were to be remedied by a cleaning up of the slums and the construction of sanitary, clean and wholesome buildings, the incidence of venereal infection would strike a new low.

**Vaccine Treatment of Asthma in Childhood.**—Realizing a lack of completely favorable results in the plan of protein desensitization by injection of specific skin reacting allergens, Naef used a plan of nonspecific bacterial protein desensitization as a therapeutic procedure in sixteen asthmatic children from 14 months to 12 years of age. Intramuscular doses of stock mixed pertussis and mixed catarrhal vaccine were given for nonspecific protein desensitization. The plan of administration of the vaccine entailed the giving of one-third and two-thirds cubic centimeter doses forty-eight hours apart followed by three 1 cc. doses at intervals of forty-eight hours and three 1 cc. doses at weekly intervals. Presence of dyspnea was regarded as the only contraindication to the administration of the vaccine. The results of the treatment showed 68 per cent complete inhibition of allergic spasm and 18 per cent improvement of the condition both in recurrence and in severity of seizures; 14 per cent showed no response. More than 75 per cent of the Mantoux tests were negative, showing a low incidence of tuberculosis in the asthmatic child.

**Headaches of Menopause.**—Assuming that the anterior hypophysis undergoes an abnormal physiologic hyperplasia following castration and during the menopause, Reel and Lewis believe that the explanation of the headache so often complained of lies in the fact that the pituitary gland is almost completely surrounded by bone. It lies, so to speak, in a box within a box, thus preventing any marked expansion from taking place except by greatly increasing the tension within the sella. This in all probability produces headache in the same manner as that induced by increased intracranial pressure. Pituitary headaches may be entirely occipital or suboccipital in type. Some patients will complain of occipital pain transmitted bilaterally to the frontal or temporal areas. Quite commonly one entire side of the head is involved. A dull, heavy distress located behind the inner angles of the eyes is frequently encountered. The pain, regardless of type, is usually severe. It may be lancinating or develop as a deep seated, heavy, dull ache. In fourteen of the nineteen patients whose chief symptom of the menopause was that of very severe headache, an abnormal amount of gonadotropic substance was demonstrated in the blood, according to the Fluhmann technic, prior to irradiation. The roentgen treatments were given with 200 kilovolts at 50 cm. distance, with 0.65 mm. of copper and 1 mm. of aluminum as a filter and an 8 cm. mask. A total of 1,000 roentgens was used, divided into two exposures of 500 roentgens each administered a week apart and on opposite sides of the head. Other than a temporary alopecia in two patients and a slight transient parotitis in one, no complications or ill effects were encountered. Following irradiation, fourteen of the nineteen patients showed a marked degree of improvement. Three of the remaining five were improved to some extent, while the remaining two received no benefit. The authors believe that the total dosage has an inhibitory effect on the activity of the hypophysis. If this is true, it would seem safe to assume that the result has been a diminution in the size of the gland and a subsequent lessening of tension within the sella. Since the chief complaint of headache tends to disappear under this type of management without the aid of other forms of therapy, the conclusion may be justified that the pituitary is a highly probable factor in the causation of certain types of headache peculiar to the menopause.

understanding of the specialty in question; an active experience of not less than eighteen months in hospital clinics, dispensaries and diagnostic laboratories recognized by the Council as competent in the specialty; examinations in the basic medical sciences of a specialty as well as in the clinical, laboratory and public health aspects; (3) an additional period of not less than two years of study and/or practice.

Virchow once said that true science was the power of performance and society has the right to ask of any person purporting to be a specialist Is your knowledge and training in consonance with the general average of intelligence and knowledge as it pertains to your specialty?

As medical science has progressed there has been a tendency toward fractionalization of specialism in the fields of internal medicine and surgery. To cite a few examples endocrinology, cardiology, allergy, gastroenterology and, in surgery, plastic and traumatic surgery and proctology. If special subdivisions of specialistic training appear to be necessary, it would seem imperative that these specialists must first qualify in the general broad field of the specialty, medical or surgical.

It is apparent that under no circumstances should there be any diminution in the standards set up for the qualification of specialists and in like measure we must be on our guard against any such thing as multiple certification or certification by one or more of the boards of certification.

Perhaps one of the most important developments in connection with the program of the certification of specialists will be the extension of graduate medical education. This would make available all the clinical facilities of the country by adequate mobilization of the medical resources of the various hospitals. It would have a most profound and far reaching effect on the public in that within an incredibly short time the facilities for the adequate teaching of specialism would be so tremendously enhanced that there would be set in motion a public attitude of mind which would make one confident that the inadequately trained, self-assertive specialist would be in the process of extinction.

The question of research with regard to a candidate's application for certification is a difficult problem. It would seem wise that the question of research work should not be part of the examination of a candidate for certification. Discoveries in medicine, as a rule, cannot be formulated nor can their success be purchased either by equipment or by money. If one could be certain that by requiring every candidate to do some work in research we might stimulate or create a Koch, an Ehrlich, a Pasteur, a Lister, a Harvey or a Banting, the results would certainly justify the means. Genius, however, is such an occult, mysterious thing that it springs fully developed from a single room and a microscope, as from a most elaborately and adequately equipped laboratory. Graves and Stokes with eight beds, Harvey with anatomic material, and Jenner with a country cow-stable created and developed that cerebral mechanism which goes with genius and which makes fundamental discoveries in medical science, which could not be purchased either with money or with institutional equipment.

A few months ago the Surgeon General of the Army and the Surgeon General of the Navy indicated in a public address the number of trained, competent physicians and surgeons that would be needed in the event of another war. On that occasion I had the temerity

to make the statement that if unhappily the time ever came that another war descended on the people of this country the American Medical Association was prepared, by means of its facilities, to indicate the qualifications of the medical personnel required. In a short time, with all the twelve certifying boards harmoniously functioning, there will be created such an authoritative roster of medical personnel as to make it possible to mobilize in an incredibly short time any required number of adequately certified physicians for the performance of a war time job.

116 East Fifty-Third Street.

## RESIDENCY IN HOSPITAL ADMINISTRATION

AN EXPERIMENT IN TRAINING GRADUATES IN  
MEDICINE FOR THIS SPECIAL FIELD

J. J. GOLUB, M.D.

Director, Hospital for Joint Diseases  
NEW YORK

There are two methods by which a qualified graduate in medicine can be trained as a hospital executive: (1) attending a special training school, which offers prescribed courses, and (2) working and studying in a hospital, under the direction of its executive head.

This does not mean that a person with a sound general, special or nursing education—but without a medical education—would not be qualified for training and ultimately for leadership in hospital administration. That this paper outlines a program only for graduates in medicine is due to the fact that the Hospital for Joint Diseases, after five years of careful consideration, made the experiment of creating the position of Resident in Hospital Administration. The qualifications described elsewhere were met by the successful candidate, and the program of training outlined in this article is being followed.

Hospital administration is complex and diversified, and its interests must extend over much of the domain of man's social and economic life. To the hospital's interest in disease and its treatment, new times have added a way of thinking about the social and economic influences affecting the patient, his home environment and background, his welfare at the hospital, his fate after discharge, and the situation of his family during and after his illness. The social processes of the community as a whole and the growing interest in public health have led the hospital to add to its responsibility a share in the community's efforts to fight off social deterioration.

Under the influence of this expanding concept of hospital aims, the work of hospital administration goes more and more beyond its walls. It now involves the articulation of the hospital with the community, government, central chests, federations, foundations and welfare agencies, and with the medical, dental and nursing professions. It is concerned with and affected by the problems facing the medical and nursing professions. Such questions as costs of medical care, economic burdens of the physician, hospital and outpatient department abuses, open or closed hospital policy, health insurance, periodic health examinations, socialization of medicine, legislation affecting medicine, specialization and the family physician, ethics, cults and the standards of medical education, all of which

**Suppurative Pericarditis.**—Bigger states that suppurative pericarditis is not a rare condition but is infrequently diagnosed because in the absence of characteristic symptoms it is not suspected and is not looked for. It is never primary but is always secondary to infection elsewhere except when it results from direct trauma. The most important antecedent infections are pneumonia with empyema and osteomyelitis with an associated infection of the blood stream. Since recovery is rare without adequate drainage, it is essential that physicians make frequent, careful examinations of the cardiac area in patients with severe infections. This is especially important in intrathoracic infections or in distant infections with associated bacteremia or septicemia. Eight cases of suppurative pericarditis treated by surgical drainage are reported. Four patients recovered and four died, but only two of the deaths could be attributed to the pericardial infection.

**Conditions Simulating Sinus Disease.**—Slack points out that during the last few years the paranasal sinuses have been the subject of much discussion in medical literature. All manner of therapeutic agents from diet to climate have been advocated for their treatment and a great many modifications of the generally accepted operative procedures have been recommended. The widely divergent opinions and varied advice are a fair indication of the importance of this problem. Many times the specialist is consulted about "sinus trouble" by patients coming of their own accord or referred by the family physician, when in reality the symptoms are caused by some general systemic disorder or certain local conditions entirely unrelated to the paranasal sinuses. There are too many mutilated nasal cavities that furnish an added source of irritation and tend to destroy the faith of the poor sufferer in the medical profession. Before any therapeutic measures are instituted or operative procedures advised it is absolutely essential that the patient be given a thorough general medical examination and diagnostic study. A few specific conditions most commonly simulating sinus diseases are neurasthenia, allergic conditions, infected teeth, refractive errors and eyestrain, syphilis, intracranial conditions, disturbances of the endocrine glands, improper diet, undulant fever and encephalitis. The author gives a typical case of each.

**Pathology of Syphilis.**—Since 1911 Almkvist has been studying the microscopic changes in different kinds of syphilis. These investigations have led him to formulate certain general laws or rules, of which the three principal ones are: 1. In each kind of tissue the spirochetes bring about a histologic reaction characteristic of the tissue in question, but different from the reaction in other tissues. 2. The changes induced by the syphilitic process in each kind of tissue are of a distinctly uniform nature through the whole course of the disease. They are the same in recent and in old standing syphilis and cannot be separated into three stages, as in Ricord's grouping. 3. The different clinical manifestations of the syphilitic lesions are not due to differences in the reactions between the spirochetes and the tissues, since the tissues react uniformly throughout the whole course of the disease, but rather to such factors as the varying location of the spirochetes, differences in the degree of immunity, toxin-antitoxin reactions and nutritional disturbances. His investigations have enabled him to distinguish six different types of tissue changes localized in the epidermis, connective tissue, lymphatic vessels, blood capillaries, highly developed organs and blood vessels. The individual tissue alterations remain uniform throughout the entire course of the disease. They do not give any impression of conforming to different stages, or periods, in accordance with the evolution of the disease. This uniformity of the histopathologic changes does not prevent one from distinguishing certain periods in the course of syphilis. The localization of the spirochetes and, in consequence of this, the localization—not the structure—of the syphilitic changes is not the same throughout the whole course of the disease. Further, there are certain changes which can be seen only in the late stages of syphilis. Consequently the author has been able to distinguish, instead of Ricord's three periods of primary, secondary and tertiary changes, four periods on a real pathologic basis: initial or humoral syphilis, hematogenous syphilis, serpiginous, creeping syphilis and old degenerative syphilis.

 \*Katholysis in Treatment of Retinal Detachment: Preliminary Note. H. B. Stallard.—p. 35.

**Katholysis in Treatment of Retinal Detachment.**—Stallard believes that in favor of katholysis is the precision with which its effect on the ocular tissues is circumscribed. There is no extensive spread of the current and on this account no damage is inflicted on other intra-ocular structures remote from the area of operation. After katholysis he has not yet seen such complications as cyclitis, iritis, cataract and optic neuritis, which follow in some cases of retinal detachment treated by other surgical diathermy procedures. As yet he has treated too few cases to give any fair statistics of the results of treatment. His impression is that katholysis is of value in anterior dialysis in the lower half of the retina. The operative reaction is well localized and does not spread to the ciliary body and with the help of the vitreous and gravity the choroid-retinal adhesions seem to be firm enough to hold the retina in

seriously engage the interest of the medical profession, are of vital interest to the hospital. Such questions as nursing education, supply, demand and distribution of nurses, grading of nurses' schools, group nursing, nurses' and students' hours of work, nursing standards and duties, and nurses' earnings, which are of primary interest to the nursing profession, also deeply concern the hospital.

Hospital administration is intramural, since it requires effective and well coordinated internal institutional operation. The work involves medical, sociological and business procedures and technics applied by the usual professional, administrative and technical hospital departments and coordinated by the executive head. For hospital administration to be progressive requires continual exercise of the kind of resourcefulness and

administration and in closely allied fields. The social sciences, architecture, engineering and selected current medical literature are included. During the resident's service he is to receive encouragement to write on hospital subjects and to prepare material for a thesis.

The term of service is three years.

During the first year the resident devotes himself to the study and supervision of administrative policies and procedures (nonclinical) of :

1. *Admitting Department.*—Its organization and policies; routine preadmission examination, with special emphasis on the examination of children to control admission of patients with contagious disease; provisional diagnosis; determination of eligibility from the points of view of admissible conditions, economic status and zone; classification and assignment of patients to suitable services; reservations for private and ward admissions, and condition of waiting list; attention to patient's

The Schedule of Service

		A Three-Year Plan*					
First Year		1937	1938	1939	1940	1941	1942
JUNIOR RESIDENT IN HOSPITAL ADMINISTRATION.....	Study and Supervision of Departmental Group A	A	B	C	A	B	C
1. Admitting department							
2. House staff							
3. Emergency and ambulance service							
4. Deaths and autopsies							
5. Record department and library							
6. Surgical operating rooms, maternity delivery rooms and anesthesia service							
7. Nursing service							
8. Social service department							
Second Year							
INTERMEDIATE RESIDENT IN HOSPITAL ADMINISTRATION.....	Study and Supervision of Departmental Group B	—	A	B	C	A	B

11. Pharmacy							
12. Other professional services							
13. Outpatient department							
14. Dietary service							
15. Housekeeping and laundry							
16. Engineering and maintenance of plant							
Third Year							
SENIOR RESIDENT IN HOSPITAL ADMINISTRATION.....	Study and Supervision of Departmental Group C	—	—	A	B	C	A
17. Personnel administration							
18. Accounting and finance							
19. Purchase and issue							
20. Medical staff organization							
21. Board of trustees							
22. Community relationship							
23. Planning and construction							
24. A thesis							

\* A refers to the appointee who will serve as Junior Resident in 1937; as Intermediate Resident in 1938 and as Senior Resident in 1939, graduating at the end of that year. B refers to the appointee who will begin his service in 1938 and who will graduate in 1940. C refers to the appointee who will begin his service in 1939, and so on.

vision that lead it to originate and to employ (not without caution) new methods and new procedures offered by modern science.

A hospital executive must know all these fields. Hospital administration is a specialized career, and training and experience can be offered only to those who have been properly prepared. In considering candidates for the post of Resident in Hospital Administration, the Hospital for Joint Diseases felt constrained to make the following requirements:

1. Graduation from a grade A medical school.
2. Two years' general internship in a hospital with a bed capacity of at least 200.
3. Reliable testimony and observation as to personal qualities, such as aptitude for administration, character, capacity to learn, resourcefulness, vision, social mindedness, ability to work hard and well with others, and poise.
4. A desire to make hospital administration a life work rather than a means of finding temporary employment.

The method of training acceptable candidates consists of the gradual assignment of administrative responsibility, reading and study of literature on hospital

valubles and clothes; notification of visiting and house staffs of new admission; prompt first visit to patient on the part of visiting and house staffs; critically sick list and notification of family; discharges, transfers and ascertainment of causes requiring patients to remain in the hospital over unusually long periods of time, say two months or longer.

2. *House Staff.*—Organization and procedure for the examination of candidates for internship and clinical residency; equitable distribution of work; general deportment and appearance; promptness in answering emergency and other calls; proper use of supplies; consultation with members of patients' families; informing visiting staff of schedule of operations; new admissions and conditions of patients; emergency laboratory and x-ray examinations; attendance at outpatient clinics; attendance at hospital lectures.

3. *Emergency and Ambulance Service.*—Prompt attention to and proper recording of accident cases; notification of police; essential supplies in emergency room, such as antitoxin; policies pertaining to private and public ambulance service.

4. *Deaths and Autopsies.*—The study and supervision of the issuance of death certificates; facts concerning sudden deaths; notification of coroner; obtaining permission for postmortem examinations and their timely performance; condition of bodies and embalming; condition of morgue; dealings with undertakers.

THE PHYSICIAN AND THE TRAFFIC  
PROBLEMLOWELL S. SELLING, M.D.  
DETROIT

The recent literature on surgery has been full of references to the various problems confronting surgeons due to traffic accidents. New types of fractures have appeared and new technics have been devised to handle situations caused by the increased use of the automobile. In spite of the fact that the physician and his allied specialist the psychiatrist should be deeply interested in this subject, it seems that their eyes have scarcely been turned upon it. The manufacturers themselves have recognized the fact that the human element is an extremely important one in causing accidents, and law enforcement officers, judges and traffic administrators, particularly some of those at Harvard University, have emphasized the point that the physical and mental condition of the driver should be studied and that the problem created by physical and mental abnormalities in the driver is deserving of much more attention. Whenever there is a grave increase in the number of accidents in any community, a cry is raised by the newspapers and others for more physical and mental examinations, and in many states some routine physical examination, at least to the extent of rough tests of vision and a medical questionnaire, has been invoked and has been found to be of some use in culling out dangerous drivers. In other states where no formal examination is demanded, simple reading tests have been devised so that the optical capacity of the candidate for a license can be simply tested by a police officer or other untrained person.

Why the physicians have permitted this testing activity to pass beyond their control, as it seems to have done, is a question difficult to answer. Certainly physical examinations, particularly those of the eye (a most difficult organ to test) are in the rightful sphere of the physician and many of the criticisms of the examination for the operator's license as it is now administered could be done away with were these examinations carried out by persons interested in therapy rather than in mere elimination. Most of the resistance to the proper licensing of drivers is based on the fact that whenever possible a car owner or a member of his family who has reached a sufficient age and is grossly physically capable of driving should have the right to drive. Any infringement on this right is considered an infringement on liberty as the American people see it. Naturally, in such criticism the physician should be interested and is very likely to concur. But if a man is found with defective eyesight or defective physical make-up so that he would not be a safe risk on the road, it would be better for that individual to be studied with the view of correcting his difficulties, so he might be remade into a safe driver. Then in such a situation there would be no infringement on his right to operate a motor car.

The chief reason for criticism of the tests proposed in some states and now given to drivers in others, which should be of interest to physicians, is the fact that these tests in themselves do not separate the good from the bad driver. Many of the driving difficulties are due to emotional handicaps or arise from some

temporary physical condition that is correctable or that might not occur again in the same individual during the rest of his life. Under these conditions the mere physical examination, a mere check-up of the eyesight, or a brief psychologic test, such as the Binet or some simpler test, would fail to reveal why the man under consideration had his accident or why he is a chronic law violator. Until physicians themselves give these examinations, compile data and show just where the line must be drawn between adequate and inadequate physical capacities, licensing by means of physical and mental tests will be more or less of a farce. For instance, I know of one man who has two artificial arms which are so constructed that he is able to steer and control an automobile. This man has now been driving for upward of twenty years and because of the care which he uses and the type of highways where he drives he has never been in any trouble with the law or had an accident. A mere physical handicap is no contraindication to driving, and it requires the decision of an experienced and highly trained individual to make a determination.

The features which the physician must consider when mapping out plans for making examinations for driver's license, or examining offenders or persons involved in accidents, from the physical and mental standpoint, are threefold:

## THE GENERAL PHYSICAL CONDITION

First is the general physical condition, which is not extremely important, although at the Recorder's Court Clinic in Detroit there are on record several cases in which a known cardiac patient has suffered a collapse and has run into a safety zone, thus injuring other riders in the car with him, and also cases of persons suffering with debilitating diseases, such as tuberculosis, who when they have driven for long periods of time without a rest have gone into a serious fatigue condition, which impaired their alertness and resulted in an accident. In several recent addresses made to law enforcement officers, I have emphasized to them the fact that a physician's certificate as to the organic soundness of the candidate for a driver's license can easily be requested by licensing officials even though the law does not demand it. Most persons are certain that they have no physical handicap which would disqualify them and are only too anxious to secure evidence that they are well able, at least from the physical point of view, to drive a motor car. The matter of expense is not great, for most family physicians will grant this service for a minimum fee, and in many communities where enough cases can be referred, private physicians have signified their willingness to make special terms for such a service.

It might also be pointed out that such a physical examination would serve as the general health check-up which we as physicians are so anxious to have our patients submit to at reasonable intervals. In the case of the family physician it is an additional service he may render to families which require his services at quite infrequent intervals and which might lose touch with him.

There are one or two special features that should be noted. One, particularly, is the presence of a convulsive state. Most idiopathic epileptic patients are known to their local physicians, particularly to their family doctors, for usually they are using phenobarbital or some other sedative drug to control the rather

unpleasant episodes that they have. The known patient with serious epilepsy should unquestionably be curtailed in his driving capacity. Those whose convulsions can be controlled must realize that they must continue their treatment in a very serious manner if they are to use a motor car, for the motor car is a dangerous apparatus to handle if the driver is apt to become unconscious at intervals. Cases of petit mal frequently pass through a physician's hands without being recognized because no complaint is made by the patient. A check should carefully be made to see whether any of the symptoms of the minor attacks are present. The Psychopathic Clinic of the Recorder's Court has had two cases out of the last hundred in which petit mal was detected even though the individual himself did not know he had this condition.

The neurologic examination must by no means be neglected. The following is a case illustrating its importance:

A youth, aged 19 years, of athletic build, 5 feet 5 inches (165 cm.) in height and weighing 138 pounds (63 Kg.), was physically normal. His chest was symmetrical, his heart normal and his blood pressure slightly low. The neurologic examination revealed that while the cranial nerves were normal there was a slight swaying on the Romberg test, and marked tremors of the facial muscles, tongue and extended hands. The boy was ataxic and clumsy, with poor coordination. The heel to heel test was not as seriously atypical as the finger to nose test. A report was made to the judge that the boy's coordination was so poor that he would be unable to manipulate a car properly, and his license was revoked.

In another case, however, in which the coordination was less seriously impaired, the man was given some of Franz's rehabilitation exercises with the result that there was sufficient improvement so that there was no need to curtail his driving activity.

#### THE EYE EXAMINATION

The second type of examination is the eye examination. For all intents and purposes, the family physician who has some inexpensive equipment should be able to aid immensely in detecting gross eye defects that will obviously impair driving capacity. The proper use of the Snellen eye chart, the Ishahora color vision test, one of the conventional astigmatic charts, and the ophthalmoscope will usually suggest the presence of impaired vision. While it is quite true that some visual impairments, which might interfere with a person's driving capacity, do not always appear when the patient is given these simple tests, nevertheless cases of muscular imbalance, impaired physiologic function and deviated stereoscopic vision usually make themselves manifest on careful tests of visual acuity.

The physician who is really interested in this work might add to these tests of visual acuity the use of a protractor held horizontally before the eye around which a pencil is passed, thereby testing the breadth of the visual field.

In the experience of persons in giving careful tests to drivers, the number of cases of limited visual fields or barrel vision is very small, and these cases are usually accompanied by other symptoms of organic or functional nervous diseases. I would advocate the use, in the examination of accident-prone drivers, of local ophthalmologists to a greater extent than has been done.

There is no reason why the ophthalmologist in private practice cannot devise a simple way of detecting most of the deviations in vision or optical functions that would interfere with driving. It is true that in a clinic directly responsible to court more involved tests

can be given which pertain less to disease than to psychologic function, but even here the use of a Keystone stereoscope, the campimeter and the slit lamp should be entirely adequate to enable traffic law enforcement officers to become aware of the need to call in the ophthalmologic consultant for licensing tests and for expert advice to the courts. In many cases treatment is definitely indicated. A case in point is the following:

A Negro, aged 26, married, Georgia born, was arrested for using and displaying another man's license, and it was the judge's intention to give him a slight sentence and permit him to go on his way. However, it occurred to the judge that it might be an intelligent thing to have the man examined, and he was referred for such examination, which revealed that physically he was in generally good condition except for extremely bad teeth, but the examination of the eyes revealed an extensive pannus over the right eye. The vision was markedly impaired.

This man would have continued to drive a car and on examining his record we found that he had been in much trouble before. It was easy to point out that, for no other reason than the eye condition, his driving activities should be sharply curtailed until he had proper treatment from an eye specialist.

#### MENTAL DEVIATIONS

The third place where the physician can be of aid is in detecting mental deviations. While specialized experience in examining the attitude and psychiatric capacity of the driver is as necessary here as it is in treating mental patients, the family physician's knowledge of the individual's scholastic ability and his home conditions should be of extreme value in advising about successful driving. While at the present time our knowledge of the mental factors behind bad driving is extremely limited so that it would be unwise for the physician to take upon himself too much in the way of advising along these lines, it cannot be gainsaid that the family physician who knows that the individual has done very poorly in school, that he has been considered for commitment to an institution for the feeble-minded or the insane, or who knows that the patient's attitude is extremely antisocial and, perhaps, that he has been a problem in the family for some time, can advise such an individual not to apply for a license and, in addition, keep him under observation so that he will not cause injury and death because of his violation of the physician's instructions.

The examination of the mental make-up is distinctly a sphere in which the intelligent psychiatrist should find his services required. The understanding of the make-up and the attitude of the accident-prone driver or the violation-prone driver is not a simple procedure and too little research has been done along these lines; but, if psychiatrists will examine the work that has been done already and will show an interest in research along these lines, their services will undoubtedly be required in the capacity of advisers to licensing agencies. Certainly the psychiatrist and the physician are in an excellent position to devise treatment and means to put partially incapacitated drivers on the highway and to prevent those who are too sick mentally or physically from driving until such time as they are cured or their condition is substantially under control.

A neurosurgeon in private practice came to me a short time ago very much up in arms because he found that a patient of his, who had just been operated on for brain tumor and who had had a substantial part of

5. *Record Department and Library.*—Prompt and legible recording on charts, abstracting, indexing, filing and nomenclature; study and uses of printed forms; the daily census; medical library.

6. *Surgical Operating Rooms, Maternity Delivery Rooms and Anesthesia Service.*—Thorough preoperative physical examination of patients, with emphasis on precautions, and careful recording; schedule of operations; recovery room; vigilance over postoperative patients, attendance during recovery from anesthesia, temperature of room, drafts; postoperative infections and sequelae; condition of apparatus; proper preparation and sterilization of material, intravenous sets and solutions; bacteriologic examination of sterile material, instruments, water and surgeons' finger nails; blood transfusions and donors; obstetric technic and precautions; labor and delivery rooms, care and identification of new-born; emergency lighting; resuscitation apparatus.

7. *Nursing Service.*—Organization; standards and service to patients; ratio of patients to nurse; standing orders and procedure; floor, emergency and general supplies; group and special nursing; nursing education; registry; general professional and economic problems of nurses.

8. *Social Service Department.*—Aims and organization; relationship to medical staff, clinics, wards, patients and their families; convalescent care; home medical service; religious service and entertainment of patients; direct relief; contacts with other social agencies; occupational therapy; patients' library; volunteer service.

During the second year, the resident studies and supervises the administrative aspects of:

9. *Laboratories.*—Pathology, bacteriology, hematology and chemistry; routine and research activities; training technicians; animal house and animal operating rooms.

10. *X-Ray Department.*—Diagnosis, therapy, radium and photography services; bedside roentgenograms; cystoscopy; x-ray burns.

11. *Pharmacy.*—Service to floor and outpatient department; the formulary; safekeeping of narcotics and alcohol; appropriate labeling and compounding; "patent" medicines; unapproved drugs.

12. *Other Professional Services.*—Physical therapy and hydrotherapy; electrocardiography; basal metabolism; oxygen therapy; brace department; intravenous therapy; their organization and equipment.

13. *Outpatient Department.*—Organization and policies; standards of service; restrictions as to surgery and anesthesia; zoning rules; economic eligibility of patients; admissible conditions; clinic sessions; schedules of service of visiting staff; isolation of contagious disease; hospital admission refers; follow up.

14. *Dietary Service.*—General service; special diets; food clinics; instruction; sanitation; quality of provisions.

15. *Housekeeping and Laundry.*—General cleanliness; furnishings and furniture; linen and laundering.

16. *Engineering and Maintenance of Plant.*—Care of machines, motors and elevators; repairs and painting; care of the grounds; heating; ventilation and air conditioning, plumbing, electricity, refrigeration; fire prevention.

During the third year, the resident is assigned to the study and supervision of:

17. *Personnel Administration.*—Personnel organization, employment and personnel practices; living quarters; recreation; salaries; hours; job analysis; employees' health and prevention of accident.

18. *Accounting and Finance.*—The budget; hospital rates; unpaid accounts; cost analysis; all types of insurance; workmen's compensation.

19. *Purchase and Issue.*—Standardization; quality and testing of equipment and commodities; policies of purchase; bids; storage and issue of supplies; inventory.

20. *Medical Staff Organization and Service.*—Schedules and assignments of visiting staff members; rounds; attendance at meetings of the medical board and its committees; allocation of beds to services; standards of medical care; prevention of accident to patients; ethics; scholarships and fellowships;

clinical departmental and postmortem conferences; the Clinical Society; the Junior Staff Society; the Alumni Association; publications and lectures; teaching; clinical research.

21. *Board of Trustees.*—Opportunities to attend board and committee meetings; policies; charter, constitution and by-laws; cooperation with the ladies' auxiliary and its committees.

22. *Community Relationship.*—Study of the incidence of disease; population movement; community surveys; participation in community's social planning; law pertaining to hospitals and medicine; new legislation; sanitary and building codes; other hospitals; welfare agencies; hospital councils and associations; central chests; federations; foundations; government; medical societies; medical schools; church, fraternal, industrial and labor organizations; publicity; preparation of annual report; fund-raising campaigns.

23. *Planning and Construction.*—General consideration; opportunity to participate in planning of new construction and alterations; building materials; equipment.

24. *A Thesis.*—An original thesis on some phase of hospital service or planning, or in fields related to hospital service.

The plan establishes three grades, Junior, Intermediate and Senior, and calls for the appointment of one resident each year to serve for three years, one year in each grade. Beginning with the third year, all grades will have been filled. At the end of the third year and at the end of each year thereafter one resident will graduate.

The resident will serve in the capacity of Junior Resident in Hospital Administration during his first year, and the period will be probationary. If he proves to have the necessary qualities, he will be promoted to the position of Intermediate Resident in Hospital Administration, and finally to that of Senior Resident in Hospital Administration. Before the end of this residency, i. e., the end of the third year, he will submit a thesis and receive a certificate of completion of this three-year service.

Residents will have complete maintenance and an honorarium of \$50 a month during the first year, \$75 a month during the second year and \$100 a month during the third year. Unlike clinical interns and clinical residents, they will wear no uniforms.

The schedule of service discussed here is organized in twenty-four departmental divisions, divided into three groups of eight departments each. Other hospitals desiring to introduce residencies in hospital administration may find it convenient to change the title of "resident" to that of "fellow" or "scholar" or to change the scheme to two grades of Junior and Senior (or by any other names), giving eighteen months of service to each, or prolong the residency beyond three years. Whatever the scheme, it is also possible to add a six to twelve months exchange service with other hospitals, thus permitting the resident an opportunity of observing the policies and practices in more than one institution.

In a large community where there is a university, several hospitals introducing this or a similar plan of training may affiliate with the university for a course of supplementary lectures on the subject matters discussed here, leading to a degree of Doctor in Hospital Administration.

The plan makes of the resident both a student and a worker, under the direction and guidance of the usual department heads and the executive head. It is hoped that the training will be intensive and that book knowledge will be integrated with direct experience of all phases of hospital management and community relationship.

When opportunities in residencies in hospital administration become generally known and widespread, they

sion, normal and prosperity periods. General occupancy figures, such as those here used, unquestionably conceal many internal fluctuations in the different departments; for example, the uncertainties of pediatric and maternity demand as compared with the relatively stable volume of medical and surgical cases and the effect of hard times on the private patients and elective surgery.

Average number of days a year in 23 hospital years.....		16.7	5.4

To general hospitals the question is presented Can there be any advantage that justifies the cost of maintaining beds that are used less than 5 per cent of the time?

The most important question is, of course. Can reserve beds equivalent to more than 25 per cent of the average daily census be justified?

## THE COST OF IDLE BEDS

Any answer to the foregoing question should take into consideration the following facts:

1. Hospitalization is probably one of the most stable of all this country's industries. The *Hospital Management* occupancy curve shows the fluctuations given in table 6. Compare these figures showing a maximum variation on the six year period of 21.4 per cent with the 80 per cent decline of production in the motor industry, which sold five cars in 1929 for each one sold in 1932.<sup>2</sup> Compare the major seasonal demands that influence industrial capacity with the minor fluctuations which the study shows in the average hospital's census.

While prosperity or the lack of it may affect hospital income, it apparently has a negligible effect on hospital volume. Under these conditions it should be possible to determine more closely how many beds hospitals really require and reduce the wasteful surplus to a practical minimum. Hospitals are always in need of money. Expenses are on an ascending scale. In one large group<sup>3</sup> the average cost of caring for a patient increased from \$40 in 1912 to \$83 in 1935. The easiest way to raise money is to save it, and the most practical way for a hospital to save is by reducing the overhead incidental to beds for which it has no use.

2. The nation's investment in general hospitals<sup>4</sup> averages \$5,000 a bed, with annual fixed charges at \$700 (\$250 for interest, \$150 for depreciation and \$350 for "readiness to serve" cost). As previously mentioned, the American Hospital Association report found that more than 87,500 beds are being maintained in this country in excess of needs, representing frozen capital of over \$437,000,000 and annual fixed charges of \$61,250,000.

3. The record of general hospital bed occupancy by states for 1935 as shown by the American Medical Association statistics reveals only seven states with an occupancy of 70 per cent or over (Connecticut, Louisiana, Maryland, Massachusetts, Colorado, New York and Rhode Island); seventeen states range from 60 to 70 per cent and twenty-four from 40 to 60 per cent.

4. Over half a million beds are now being maintained in this country in nongovernment hospitals and, notwithstanding about 145,000 idle beds in 1935, new beds are being added at the rate of seventy-seven each day according to statistics for the year 1936 compiled by the Council of Medical Education and Hospitals of the American Medical Association.<sup>5</sup> As Dr. Haven Emerson<sup>6</sup> has said, "It seems preposterous to continue such relative idleness as is represented by an average occupancy of but 60 to 70 per cent of hospital beds."

## CAUSES FOR IDLE BEDS

The chronic malady of overhospitalization appears to be due largely to the following causes:

1. Hospitals have failed to pool their resources. In every community, while hospital care is a common problem financed out of the community purse, it is rarely approached as a common problem. There is seldom more than a semblance of joint action. Many hospitals with many policies promote conflicting activities, each as an individual unit rather than as a unit of common service.

2. The machinery responsible for the existence of too many hospitals and too many beds seems sadly in need of overhauling. The methods long used to estimate the needs of a given district or a given hospital appear faulty and the long accepted yardsticks calling for a specific number of beds for each thousand of population—five or six beds for acute cases per thousand for large cities and three or four in suburban and rural areas—have proved misleading. Perhaps most disastrous has been the lack of any curb on the ambitious hospital which builds without regard to facilities

TABLE 5.—Relation Between Crowding and Reserve Beds

23 hospitals had 83% occupancy on	10 days or less
6 hospitals had 83% occupancy on	11-20 days
7 hospitals had 83% occupancy on	21-30 days
3 hospitals had 83% occupancy on	31-40 days
2 hospitals had 83% occupancy on	41-50 days
2 hospitals had 83% occupancy on	51-60 days
2 hospitals had 83% occupancy on	61-81 days

TABLE 6.—Fluctuation Shown by Occupancy Curve

In 1931 a fluctuation of 8.7%, from 56.8 to 67.5%
1932 a fluctuation of 9.9%, from 51.1 to 61.8%
1933 a fluctuation of 2.8%, from 54.4 to 57.2%
1934 a fluctuation of 4.3%, from 57.7 to 62.0%
1935 a fluctuation of 7.2%, from 58.6 to 65.8%
1936 (incomplete) of 8.6%, from 63.9 to 72.5%

already available or conservative appraisal of the volume of work to be done.

3. The individual hospital is frequently unable to pool its reserve beds because of a lack of elasticity in plan and policy. Each department, medical, surgical, maternity and children's, has its own separate quota of beds and maintains its own reserve. Thus it is difficult for a crowded surgical service to overflow into

cannot fail to attract properly qualified persons. With this, the problem will arise of finding suitable places for them. It is not likely that even the most able would be ready to assume the responsibilities of executive work as heads of large hospitals, but they would be prepared to head small hospitals or to become assistants to executive heads of large hospitals, or heads of dispensaries or diagnostic clinics, and to be advanced on their records to greater responsibilities and higher positions.

1919 Madison Avenue.

## PHILOSOPHICAL COMMENTS ON EXAMINATIONS

HOWARD T. KARSNER, M.D.

CLEVELAND

### APOLOGIUM

Many of the facts about examinations are well known to teachers, but it is difficult to analyze those facts or to synthesize them in a manner that can be designated as truly scientific. Furthermore, some of the facts are observed through a tinted glass, the jaundiced yellow of prejudice or the rose of gentle kindness, and some are seen through the clear lens of objective detachment. Thus, at the present time it seems necessary and wise to employ the philosophical rather than the strictly scientific line of approach. To paraphrase Lippmann, the views expressed represent an attitude toward examinations "which, when it becomes articulate and explicit, may be dignified as a philosophy." The purpose of this paper is not so much to discuss details of methods as to emphasize anew some aspects of the matter that appear to be of broad interest. The examination has a valuable place in the program of education and training. The teaching staff often looks on examinations as a routine and unpleasant duty rather than as a major function. There are topics related to types of questions, forms of examination, origins and qualifications of the examiner, preparation and attitudes of the candidate, grades and honors, and responsibility of the professional schools to the public, all of which deserve consideration.

### ART AND SCIENCE

There is much talk about the personality of the physician and other related qualities that play a part in the practice of medicine. It is suggested by implication at least that these qualities and even those elements which go to make up character can be taught in the medical schools. Indeed, the statement has been made that character and power of expression may be worth more than medical knowledge. It must be agreed, however, that character and personality are inborn and inherent parts of the psyche. They may possibly be modified by environment, cultivated by precept and improved by maturity, but it is doubtful that they can be instilled by teaching. Even though they are intangible and not subject to exact measurement, they should be given appropriate weight in the selection of students of medicine, for they are essential to happiness and usefulness in the practice of the profession. With no underestimate of the significance of character and personality and all that they imply, and with a full appreciation of the wisdom of fostering them during the

courses in medicine, it may be said in no uncertain terms that the chief function of the schools of medicine is to teach medicine. This is not the place to discuss methods of teaching, the emphasis on learning rather than teaching, or other technical aspects of the subject, but it is the place to emphasize the opinion that schools of medicine have an inescapable duty to provide adequate education for a career of real service. Any suggestion that the art of practice is distinct from the science of medicine is false. Fundamental to that art and essential to it is science. The art without science is form without substance. The schools must safeguard the public. They must maintain ideals and protect principles. They must be able to point with reasonable pride to their product. There are certain ways by which these accomplishments can be determined, but the most conclusive is through the medium of examinations.

### AUXILIARIES TO EXAMINATIONS

Certainly, while the student is in the medical school and in more or less close contact with the teaching staff, observations of his work may be helpful in the final evaluation of his merit. The periodic tests, however, are of at least as much, if not more, value to the student in the determination of his own progress as to the instructor in estimating the acquisition of knowledge and its uses. The fact that a student can remember and utilize information for a week or two is no real guide to his mental equipment or to that permanence of its content which is essential to professional training. In general, those who do well in periodic tests also do well in final examinations and the converse is often true. There are, however, many exceptions, and the evaluation of progress on the basis of periodic tests alone is inadequate and unjust.<sup>1</sup> These dogmatic assertions do not exhaust the subject. It is reasonable that all sources should be drawn on for information as to the students' merits. Even in the schools of moderate and small size it is impossible for the department head to know all the students well. The junior members of the staff have an intimacy of contact that is not available to the most genial of professors. In spite of their presumed immaturity and supposedly pitiful lack of experience, the opinion of these junior staff members should be given a considerable weight in the final judgment of the students' ability, even although the wise professor may do so with his tongue in his cheek. Subsequent events may force the professor to place his tongue abruptly in its normal position. All this means that a staff judgment is more to be relied on than an individual judgment.

### EXAMINATIONS AS A PART OF INSTRUCTION

A platitude states that we learn by mistakes. It is unfortunate, however, that most human beings must suffer from several mistakes before the lesson is well learned. Another platitude says that anatomy must be forgotten several times (the number seems to vary from generation to generation) before it is learned. If this were true of anatomy, it should be equally true of all other subjects in the curriculum; but as a matter of fact it is true of none. Nevertheless, and perhaps equally platitudinous, it is recognized that there must be many repetitions and the most valuable of these repetitions is that necessary in preparation for a final

From the Institute of Pathology, Western Reserve University School of Medicine.

Read before the Thirty-Third Annual Congress on Medical Education and Licensure, Chicago, Feb. 16, 1937.

1. The problem of the unannounced quiz obtrudes itself here. This is a pedagogic method that may be of value in lower schools but is unworthy of the ideals of a university form of education. It is not in harmony with that academic freedom which should apply to students of university grade as well as to professors.

vacant beds on the medical floor or for a waiting list of women to be admitted to the men's wing.

4. Empty beds are deliberately maintained for causes or possibilities that should be disregarded or given their proper place of minor importance under existing conditions.

5. Too much attention is given to the tradition that when a hospital has reached an average occupancy of 80 per cent it has reached the saturation point and a new wing should be started.

6. The modern trend is toward less rather than more care of patients in general nongovernment hospitals.

In considering these points, much might be said. Certain it is that the occupancy statistics of nongovernment general hospitals during recent years prove that a more accurate method of computing the need for hospital beds should be found than those heretofore used. Again, the cost of maintaining idle beds should receive more consideration. Hospital authorities are so accustomed to carrying a large proportion of their beds empty that the ten, fifteen or twenty which are never used cause little concern, yet ten superfluous beds and what they represent in space and equipment involve an investment of from \$50,000 to \$75,000 and cost from \$7,000 to \$10,000 in fixed charges. Consider what such a sum, saved each year, would mean to any hospital and what similar savings made in all its hospitals would mean in any community, and its possibilities as a source of funds to compensate the doctors for their work in charity wards and clinics.

The failure of hospitals to pool their resources and to cooperate for community welfare has long been a subject of discussion. The 1935 Report of the Committee on Income and Bed Occupancy of the American Hospital Association says "Extraordinary effort should be made to promote closer cooperation between administrators of hospitals and their respective hospital associations and to drop such unnecessary practices and unwarranted traditional ideas in structural design and operation as may interfere with the economic security of these institutions."

If one were to ask a trustee, superintendent or surgeon why his hospital has to have 150 beds when the average census is but 100 patients, he would probably say, after reflection, "we must be prepared for peak loads, for epidemics, for catastrophes; rooms have to be closed for decorating and wards must be vacated on occasion for renovation and disinfection."

All true but, if experience is any criterion, all of minor significance with the exception of the problematic peak load. Epidemics and catastrophes can be ignored. There is certainly no justification for holding extra beds for major epidemics and catastrophes that happen once in a lifetime.

In 1918, as Red Cross field director, I spent many trying weeks in an embarkation hospital in the port of New York, when the influenza epidemic was at its height. Troop trains, transport ambulances and trucks brought a steady stream of stricken men, and for days on end 700 patients were housed in a 300 bed hospital. The problem was not beds but personnel. Conditions were not ideal, but every patient had a bed. It is significant that no scourge of like proportions has occurred in the intervening eighteen years.

Catastrophes caused by floods and other unexpected disasters occur so seldom in any section of the country as to be unpredictable and are often of such magnitude as to swamp any possible reserve hospital accommodations. No hospital is warranted in maintaining idle

beds for such a reason. When a disaster does occur, emergency hospitals are inevitably set up in other buildings.

Redecoration should never keep needed beds out of service, as the work should be done in slack months; the occasional general renovation or disinfection of a ward, if it does come at a busy time, is only a temporary inconvenience.

#### THE PROBLEM AND THE REMEDY

The evil of unnecessary hospital beds is obvious; unfortunately, the remedy is obscure. One might assume that from the hospital statistics of the last twenty years it should be relatively simple to project a curve of indicated demand for the future. The invaluable national occupancy indexes of the American Medical Association published for the past fifteen years give the number of beds and the number of patients in each hospital, and each hospital has its own detailed figures. But past averages are not safe criteria. Many trends are constant, but new conditions are constantly arising which affect average occupancy. Take the stay of the general hospital patient, which has decreased from 19 to 12.6 days between 1912 and 1936. Again, as more chronic and convalescent beds are provided and as visiting nursing service in the home is extended and tied in with the hospital, fewer days of hospital care will be required.

Moreover, it has not yet been demonstrated that the economic cycle has been overcome. If the economic swings from prosperity to depression are to be of increasing severity and duration, hospital construction should be on a more and more conservative basis.

Three steps are suggested as valuable aids in remedying a situation that cries aloud for correction:

1. There must be an estimate of the future average census and then a factor of safety set up to take care of the overloads. It is this safety factor which in the past has itself been heavily overloaded. There has apparently never been any careful appraisal of the frequency and extent of the periods of heavy demand. If the Pike's Peaks can be measured the Grand Canyons and the plains will take care of themselves.

2. The necessity for additional hospital beds in any locality should be proved from the standpoint of the community as a whole, taking into consideration such factors as general population trends, the average utilization of existing beds over at least five preceding years, and the general tendency for reduced rather than increased hospitalization; on the basis of the individual hospital's record during the same period, with particular reference to the ability of the staff to fill any proposed new beds, and on the basis of a detailed careful analysis of the hospital's occupancy statistics, department by department, for a considerable period. Probable occupancy curves on each basis, conservatively forecast, should be plotted and then harmonized. The final curve will more accurately indicate the number of required beds than any previously accepted formula.

3. The third method, of breaking down statistics into graphs showing the work of the major clinical departments, is particularly valuable. Any growth should harmonize with departmental needs. Why plan for fifty additional beds to be arbitrarily assigned to medicine, surgery, pediatrics, obstetrics? Rather plan on the basis of demonstrated need, department by department, following the principle that five beds to every four patients is sufficient for normal needs, and any construction beyond that is extravagant.

examination. This applies to factual content in particular, but it is self evident that, as subject matter becomes more firmly implanted in the conscious or even in the subconscious, the capacity to utilize knowledge in logical rational process of thought becomes more ready. Medical education and training are well served by anything that can correlate and coordinate information, integrate it in the student's mind and permit of its proper and appropriate utilization. There is a theory of education, a principle of pedagogy and a science of training, and the final examination belongs to all of these.

This line of reasoning establishes, at least in my mind, the fact that examinations constitute a part of the program of instruction, in addition to the place they must occupy in the determination of the students' capabilities. In their provision for review, repetition and recapitulation by the student, they are like the roof on the house or the capstone on the chimney. (Clichés as to the chimney and the escape of heated air are sedulously repressed.) The house is not complete without the roof, the chimney is not complete without the capstone and the course is not complete without the examination, even although the house is well designed, the chimney well constructed and the course well planned. Roofs and capstones vary in type and so do examinations. It makes no difference to the principle involved whether the examination is oral, written or both. It should, however, be a course examination to be supplemented but not replaced by the comprehensive examination.

#### COMPREHENSIVE EXAMINATIONS

Comprehensive examinations have now been in operation for a sufficient length of time to permit the conclusion that, as in the colleges, they have a valuable place in the medical schools. The instructor, in his natural enthusiasms for his own subject, is justified in regarding the comprehensive as an auxiliary to the course examination and not a substitute for it. The medical school administrator can safely look on the comprehensive as an examination of great weight in determination of the students' fitness to pass from one stage of his medical education to another, or to graduate. The educator sees that it can correlate knowledge, cover marginal fields, break down bulkheads and test relational thinking and capacity to use information in new situations with a thoroughness far beyond the scope of the course examination. Moore states that, on experimental analysis, the student who works for an examination in the distant future "learns 12 per cent better" than if he works for one in the early future, and that if knowledge rests for a year and then by review is restored to its earlier level "it will become 70 per cent more permanent than if such restoration had never taken place." Whether these figures are accurate or not, the principle cannot be successfully challenged. Its bearing on comprehensive examinations is obvious. Whether the comprehensive examination is called an admitting examination to subsequent courses or a passing examination is of little consequence in this connection. The matter of outside examiners has some bearing but will be referred to subsequently. The members of state boards of medical examiners might well give thought to their function as external examiners as well as to their obligations as protectors of the public. Many state board examinations savor of this comprehensive quality, but some fail utterly in this respect. Parts I and II of the National Board examinations

serve the educational purposes of the comprehensive review and are satisfactory for the determination of the student's accomplishment. Part III, as now conducted, illustrates the best type of correlative test. The same may be said of the qualifying boards of Great Britain and Ireland.

#### FORMS OF EXAMINATIONS

The phraseology of writers on the subject of examinations includes the terms "essay type" of question and "objective examinations." For the purposes of the medical school the essay type of question includes description, explanation, definition and discussion. Dissatisfaction with these conventional forms of questioning has at times become vociferous. The statistical evidence which the opponents bring forth is based on the wide variation in the grading of papers from a group of high schools by a number of high school teachers. With no disrespect for a fine group of teachers, these results should not be directly applied to graduate professional schools. More to the point, however, is the thought that the blame has been placed on the questions and not on the examiners, on whom it more properly belongs. In the development of education in this country, emphasis has been placed on the teaching function while the examining function has been neglected. When the time comes that the conduct of examinations becomes a major function at least coequal with the teaching function, and this is especially true in professional schools, the value of the "essay" type of question can be more adequately appraised. The objective form of question includes the yes-no, true-false, plus-zero, correct alternative, multiple choice and sentence completion types of short answer. This type of examination has the advantage of an objective grading, uniform and fair, and it can cover a wide scope of knowledge sampling. Jones points out that although questions requiring thought and problem solving may be presented, this is seldom done, that certain types of ability are not measured well if at all, and that students naturally study for this type of question without development of the capacity for expression of ideas, organization and selection of topic, avoidance of duplication and other features required for the essay type of question. What Jones says of college examinations in this respect is applicable to medical school examinations. In a limited experience with the short-answer question, it is found that often a certain amount of subjective grading is necessary. In some of the forms there is danger that a good answer might be the wrong answer.<sup>2</sup> Certain modifications are supposed to give opportunity for reasoning and judgment, but with these and the original forms the questions may readily become riddles to test wit rather than problems to test wisdom.

This part of the discussion may be considered to be too vigorous a defense of the conventional type of examination. It is meant to be a defense but is not to be interpreted to mean that tradition should be the only guide. Novelties in type may well lead the thoughtful examiner to modify his methods in important fashion, without of necessity adopting the new simply because it is new or is believed to be. Fads should not control methods of examination any more than they should be dominant in other activities of

2. The matter suggests the story, almost certainly apocryphal, of the army officer who took an examination for promotion. He was given a tactical problem and after months of study he offered a solution. This solution was not in accord with that worked out previously by the general staff and the officer failed even although his solution in this particular instance was admittedly superior to that of the staff.

The recent experience of one hospital is interesting. During the latter part of 1936 it experienced a gratifying increase in occupancy and agitation was started for "a new wing." There was a general feeling that the hospital was about ready to "burst its walls." Architects were called in to make a preliminary study and in conference with the staff and others interested were informed that there was a definite need of expansion in every direction; practically all facilities appeared to be inadequate. Fortunately, before further steps were taken, one member of the executive committee called for definite facts and statistical analyses for the past ten years. Figures on a truly comparative basis were available for a six year period. These showed occupancy percentages as given in table 7.

Further analyses showed that only the fifty-three adult ward beds had been occupied to 97 per cent capacity during 1936. The conclusion was inevitable: any general expansion was uncalled for; rather, there was merely a shortage of adult medical and surgical beds. A building program providing twenty-four such beds with a few other changes at a cost of \$75,000 took care of all needs instead of the original plan of constructing a new wing at a cost of about a quarter of a million dollars. The community was saved an unnecessary

TABLE 7.—Occupancy Percentages

Beds	1931	1932	1933	1934	1935	1936
82 Adult.....	67	69	67	72	76	87
37 Children.....	58	37	30	30	36	37
23 Maternity.....	59	55	56	56	62	66
23 Maternity, new-born.....	60	51	53	53	58	61
165 Total.....	58	57	55	58	63	70

expenditure of \$175,000 plus interest on that sum for a period of at least five years, a total saving of say \$215,000.

The outstanding experience of a 100 bed general hospital in New York City illustrates what can be done. It was perhaps the first institution in the country to be deliberately designed to take care of peak loads through a flexible plan with single rooms, small wards and solariums on all floors arranged to accommodate twenty additional beds when needed. During five consecutive years prior to the depression, its annual census averaged from ninety-one to ninety-nine patients a day, and this without material inconvenience or overcrowding. The financial results were particularly significant; the revenue from patients in those years approximated operating expenses. With overhead costs spread over capacity occupancy, a greater proportion of earnings could be spent for the refinements of service. The benign circle for successful business was set in motion. Quality promoted volume and volume reduced costs.

The fundamental problem before each hospital of the country is How many beds are needed and how shall new buildings be planned? Such figures as are here offered tend to support the theory that a general hospital should be able to handle its work if it has one reserve bed for every four patients in its average daily census.

It would appear from this limited study that the hospital's Pike's Peak is either a mole hill or a mirage, although beyond the present limited horizon there may be more and higher mountains. As to the thesis, one would appear justified in appending a tentative Q. E. D.  
512 Fifth Avenue.

## Council on Pharmacy and Chemistry

### PRELIMINARY REPORT OF THE COUNCIL MANDELIC ACID

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING PRELIMINARY REPORT, WHICH HAS KINDLY BEEN PREPARED FOR THE COUNCIL BY DR. WILLIAM F. BRAASCH. THE COUNCIL POSTPONED CONSIDERATION OF MANDELIC ACID TO AWAIT FURTHER EVIDENCE CONCERNING ITS USEFULNESS AND HARMLESSNESS.

PAUL NICHOLAS LEECH, Secretary.

### REPORT ON MANDELIC ACID

WILLIAM F. BRAASCH, M.D.

ROCHESTER, MINN.

The discovery by Clark and Helmholtz that ketonurine had bactericidal qualities paved the way for a number of therapeutic developments. The difficulties of administering the ketogenic diet, unless it was carefully supervised, were so great however that it was not generally employed. The desirability of a simpler method of establishing bacteriostatic urine was self evident. Fuller found that the bactericidal element in ketonurine was beta-hydroxybutyric acid. It was found impossible to employ beta-hydroxybutyric acid by oral administration because it is largely oxidized into carbon dioxide and water before reaching the kidney.

In the search for an organic acid of a similar nature that could be administered by mouth and excreted intact in the urine, Rosenheim discovered that mandelic acid possessed these qualities. He reported that it had no deleterious effect and that it was excreted in the urine in practically an unchanged form and in a concentration sufficient to be bactericidal. He administered mandelic acid in the form of sodium mandelate and reported that it was efficacious in most cases of bacillary infections. Since his report the drug has been further employed and is being put out by a number of manufacturers of pharmaceutical products. It has been common experience that the drug will eliminate bacillary infection in a high percentage of uncomplicated cases. Considerable experience has brought out the following data:

1. Mandelic therapy will be found bactericidal in fully 80 per cent of cases of uncomplicated urinary infection.
2. Organisms which have responded to the treatment include *Escherichia coli*, *Aerobacter aerogenes* and, in addition, members of the genera *Proteus*, *Pseudomonas*, *Alcaligenes*, *Salmonella* and *Shigella*. Helmholtz and Osterberg found that *Aerobacter aerogenes* and *Pseudomonas* were more resistant than the other bacilli. Cocci are usually affected to a lesser degree by the administration of mandelic acid to adults. Helmholtz, however, reported that it is efficacious when administered to some children. *Streptococcus faecalis* will, however, respond almost as well as bacilli. In some cases elimination of cocci has been accomplished by mandelic therapy following several intravenous injections of neoarsphenamine, or vice versa.
3. Cases frequently are observed in which mandelic therapy will produce considerable reduction in the degree of infection and improvement in symptoms, even though the bacteria are not completely eliminated from the urine.
4. As a preliminary to instrumentation or surgical treatment of the urinary tract, the drug is frequently of value even though the elimination of the infection is not accomplished.

The following principles are essential to its successful administration: 1. The amount of fluid ingested

sensible people. All credit to those who have proposed different methods, for they prevent the examination from being a time honored changeless form. The suggestions may well alter details of the conventional form, but the evidence does not as yet justify the displacement of its principles. Jones suggests that "perhaps the best type of examination contains such varied questions that students cannot easily predict from year to year the relative importance of different types of questions" and that "enough discussion questions and problems should be presented so that every student is stimulated to prepare broadly."

#### THE ORAL EXAMINATION

Although a doctor examines his patients, or at least is supposed to, he is constantly under examination by his patients, their relatives and their friends. Thus, as a medical student, he is when examined subjected to an ordeal no more severe than what will be his lot in later life. He must be ready to meet situations that confront him in school and in practice. It might be contended that since, in practice, his examination by patients is principally oral, so in school his examinations should be oral. That proposition, however, is obviously superficial, for his diagnosis and management of patients depend on prolonged and thorough study of patient and disease. Thus, his problems in school should permit of careful and painstaking analysis. In this sense the written examination gives opportunity for thoughtful consideration of problems not ordinarily afforded by the oral examination. This is in defense of the written rather than in condemnation of the oral examination. The oral examination most certainly has its place, but it is in no sense superior to the written nor should it be substituted as the only form of examination. If fatigue on the part of the examiner is of significance in the grading of written answers, it must be more so with the grading in the orals. In the former the examiner can so arrange his work that he is not subject to fatigue, but in the latter a fixed schedule over several days, as is usually the case, may give those whose names are low in the alphabetical list a rougher time than those whose names, like that of Abou ben Adhem, are at the top. Anxiety is an accompaniment of any examination, but the oral is all too likely to add embarrassment as a factor. It is true that the physician must be ready to think and act in the face of anxiety, embarrassment and other emotions, but the way he takes examinations is not always, or of necessity, a guide as to how he will meet the emergencies of a medical career.

In the actual operation of a medical school, it is likely that many of the practical examinations must be oral, but this is not true of all, especially in the so-called preclinical fields. The examiner must exercise his option, but it should be only after the most careful consideration of how best to grade the candidates.

Lest this discussion be thought to be evasive, the opinion is expressed that the written examination is of far more significance than the oral. It is unnecessary to give detailed reasons for the utility of the latter, but none or any would justify the conclusion that it should be the only form of examination.

#### GRADES AND GRADING

Capacity for organization of an answer and facility in expression undoubtedly play a part in the evaluation of the students' ability. It is claimed that those who lack these powers suffer in comparison with those who

have them. That this is unjust in medical examinations is open to question. The practitioner of modern medicine must collect his data, organize them, assign appropriate weight to each observation and arrive at a logical conclusion. The student who organizes his answers well in a professional examination is worthy of a grading superior to that of one who does not. With only rare exceptions, facility of expression is a corollary of precision of thought. The doctor must often act as a teacher in explaining the disease to the patient and in directing treatment. Facility of expression may therefore be regarded as a part of his professional equipment as well as an index of his grasp of information. The examiner must be on his guard not to be deceived by "the well turned phrase" used in shrewdness to conceal ignorance. These comments naturally apply to both oral and written examinations.

The use of grading in examinations deserves especial consideration. A mere distinction between passing and failing<sup>3</sup> may satisfy the poor student, but even the mediocre student is entitled to know how far he escaped the noose. Life is complex and, in our capitalistic system, gives free rein to competition. Survival requires meeting competition and winning. The greater the success, the greater the reward and, more important, the greater the stimulus. Even before his graduation, the medical student is confronted with the problem of securing an internship. Then or later he is also in competition for other professional posts. In the bestowal of these appointments, various factors are considered by the authorities in power; but usually academic grades weigh heavily among the items of merit. In justice to their students and to the institutions which accept them, it would seem that, willy-nilly, the faculties of schools of medicine are obliged to assign grades. This being so, the grades must be built up on as careful and precise appraisal of the student's capabilities as is possible. In some schools the students are "passed" or "passed with honors." In others those who are passed may have grades of A, B, C and D with further subdivisions. In practically all schools these distinctions are based on a decimal system of primary grading. The advantage to professional schools of translating numerical grades to other symbols is obscure to me.

As Link puts it, "the marking system is one of the few definite points at which education resembles the actual world with its systems of incentives and rewards, its mixture of justice and human fallibility." No claim is made that examinations of any type can give an exact evaluation, but they can approximate closely the relative abilities of a group or class. It may well be, as suggested by Blake, that grading should show the actual spread of qualifications rather than be made on the basis of success or failure. This is successful in the hands of the British qualifying boards. Experienced examiners attain the same objective by either method. The differential score of improvement does not meet the purposes of a professional examination and has no place in the final examinations of the medical schools, whether they are course or comprehensive.

#### CONSTRUCTION OF EXAMINATIONS

The examination must be so constructed in a professional school as to give assurance that the student has acquired the contents and facts of his courses. With

3. The temptation to insert a footnote is irresistible, for in reading "Round the Fountain" (St. Bartholomew's Hospital, London, 1927) it is observed that, although the British medical student does not use the term "funk," he has adopted variety of expression in that "plough," "pluck," "spin," "biff" and "bump" are synonyms.

in twenty-four hours must be limited to 1,200 cc. or less. 2. The  $p_H$  of the urine must be observed daily and maintained at a level of 5.5 or less. Helmholtz and Osterberg demonstrated that the degree of concentration of mandelic acid in the urine necessary for bactericidal effect decreases with the reduction of the  $p_H$ . In other words, mandelic acid when the  $p_H$  of the urine is 5 will be more bactericidal than when the  $p_H$  is 5.5. If sodium mandelate is employed, it is usually necessary to administer some drug, such as ammonium chloride, in order to obtain the desired degree of acidification. Many of the forms of mandelic acid now employed consist of an ammonium salt of mandelic acid. If, following administration of such products, the  $p_H$  is not below the level of 5.5, the addition of ammonium chloride or nitrohydrochloric acid may be necessary. When it is impossible to get the desired  $p_H$  by these methods, the administration of a ketogenic or high acid-ash diet will often bring about the desired result.

When these precautions are observed, the urine usually becomes bactericidal in the course of two or three days, and bacterial elimination usually occurs within six or seven days. It is seldom necessary to continue the therapy longer than from twelve to fourteen days. In fact, it is inadvisable to continue administration of the drug longer than this because of the possibility of renal irritation. It has been claimed that the infection very frequently recurs following a temporary elimination of bacilli. In such cases it would be advisable to repeat the mandelic therapy at intervals of a week or two.

The dosage for adults is 12 Gm. of mandelic acid administered daily. It is usually given in four divided doses during the day, before or after meals and at bedtime.

#### COMPLICATIONS

Failure of bacillary elimination may be attributable to any of the following complications: (1) chronic pyelonephritis of long standing, with advanced cicatricial changes in the renal pelvis, calices and ureter; (2) residual urine in any portion of the urinary tract; in many of these cases, however, the reduction in the degree of infection is frequently remarkable; (3) chronic prostatitis which reinfects the prostatic urethra and bladder; (4) lithiasis or tumor in any portion of the urinary tract; (5) foreign bodies, such as tubes, catheters, drains, incrustations or remnants of tissue, in the urinary tract, and (6) the occasional impossibility of lowering the  $p_H$  to 5.5 by any known means.

The following clinical symptoms are sometimes noted as the result of mandelic therapy:

1. *Nausea*.—This occurs in a small number of cases with administration of all preparations of mandelic acid, and, if present, it is advisable to reduce the dosage and then gradually increase it as the patient becomes accustomed to the drug. In some cases it is advisable to change to other preparations. The nausea is not nearly as great, however, as is that noted with the ketogenic diet, and in the former case the nausea is much more easily controlled.

2. *Diarrhea*.—Diarrhea is occasionally observed but is seldom of any consequence.

3. *Renal Irritation*.—It has been claimed that mandelic acid acts as a renal irritant, although this has not been definitely proved. Casts are often observed in the urine, but they are usually hyaline casts and are moderate in number. Helmholtz and Osterberg found a

temporary increase in the value for blood urea following intravenous injection of mandelic acid in dogs, but the value returned to normal after a few days. However, no clinical evidence of renal insufficiency resulting from administration of the drug has been observed in cases with primary normal renal function. In the presence of primary renal insufficiency the drug will not, as a rule, be efficacious because of inability on the part of the kidneys to excrete mandelic acid in sufficient concentration to be bactericidal. It may, however, cause a definite increase in the value for the blood urea in such cases.

4. *Hematuria*.—In a large series of cases of bacilluria in which mandelic acid therapy was instituted, microscopic hematuria which might have been the result of the therapy was observed in very few cases, and gross hematuria was observed in only one case. The use of mandelic acid, as in the case of any acid which is not metabolized, requires care so far as acidic substances are renal irritants.<sup>1</sup>

#### CONCLUSION

It would appear that the oral administration of mandelic acid is followed by elimination of bacillary infection in the urinary tract in a large percentage of uncomplicated cases. There is no clinical evidence to indicate that it is a severe renal irritant in the presence of a normal renal function, provided it is not continued longer than two weeks. Its use is contraindicated when there is evidence of renal insufficiency because of the possibility of causing renal irritation and since it is usually not excreted in sufficient concentration to be bactericidal.

#### NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS FORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

**CHAPPEL LIVER EXTRACT CONCENTRATED (INTRAMUSCULAR).**—A sterile aqueous solution, containing the nitrogenous, nonprotein fraction G of Cohn et al. obtained from fresh mammalian liver, preserved with phenol 0.5 per cent. The daily parenteral administration of 1.25 cc. has been found to produce the standard reticulocyte response as defined by the Council when assayed in cases of pernicious anemia.

*Actions and Uses.*—Chappel liver extract concentrated (intramuscular) is proposed for intramuscular injection in the treatment of pernicious anemia. See liver and Stomach Preparations, N. N. R., 1936, p. 271.

*Dosage.*—During relapse, the usual dosage is 3.3 cc., the contents of one vial, injected intramuscularly at seven to ten day intervals; the maintenance dose is 3.3 cc. at intervals of from three to six weeks.

Manufactured by Chappel Bros., Inc., Rockford, Ill. No U. S. patent or trademark.

*Vials Chappel Liver Extract Concentrated (Intramuscular), 3.3 cc.*

To prepare Chappel liver extract concentrated (intramuscular), finely ground equine livers are extracted several times with water. After precipitation of the proteins by heat, the liquid is concentrated in vacuo at low temperature, alcohol added to bring the alcoholic strength to 60 per cent, the precipitate filtered out, and the filtrate again evaporated. Sufficient absolute alcohol is then added to bring the alcoholic strength of the liquid up to 90 per cent. The precipitate is then dissolved in water and the reaction of the solution adjusted to  $pH$  6.4. Phenol 0.5 per cent is added as preservative and the solution is then filtered, filled into vials and sterilized by heat.

a full appreciation of the relativity of truth, especially in the biologic sciences, it is essential that the student have a comprehensive grasp of those facts which at the moment are as true as current methods permit. They constitute the background of his professional activities. The examination should decide whether or not the student has the facts sufficiently in hand to use them logically and with discrimination. This is to be emphasized particularly in the laboratory fields, where there is some danger that mental habit grooves may be established which will interfere with that capacity for the utilization of facts and ability to meet new situations necessary to success in the clinical fields. The wrong "mental set" may be encouraged by these earlier examinations. They should stimulate the right mental attitude toward facts, their appraisal, weighting, discriminating use and in every possible way encourage relational thinking. The examination should be so set that the candidate of superior attainment can be distinguished from his less talented fellows. This point of view has already been discussed in the consideration of incentives and rewards. The natural conclusion is that if a student is worthy of honors he should have them, and that his opportunity for earning them should be provided by the examiner. In a word, the examination, of whatever form, should determine factual knowledge, ability to use it, and the bestowal of honors.

#### OUTSIDE EXAMINERS

The employment of "outside" examiners, as practiced in other countries and to a limited extent in this country, is worthy of extension. Jones observes that it broadens the horizon of both teachers and students, promotes the point of view of the outer world, stimulates the students' breadth and independence of thinking, develops intellectual cooperation between instructors and pupils, and tends to raise standards in the colleges. There is little doubt that the National Board of Medical Examiners has exercised these influences and it is probable that certain of the state boards have also been effective. To paraphrase MacNider, it should be recognized that the examination may so reflect the ideals of the thoughtful examiner as to have a beneficial influence on the teaching of his subject in his own and other schools. It would be well if course examinations and the periodic comprehensive examinations in the medical schools were conducted in this manner and it is to be hoped that it may become economically and academically feasible. The Yale plan of having the laboratory comprehensive examination conducted by the clinical staff is valuable, but it is not really an outside examination because of the close association of the staffs of the two groups in a medical school. It does not meet the need for outside examiners at the end of the clinical years. Other substitutes for outside examiners are less satisfactory. It has been suggested that, when several schools are in proximity, an exchange of examiners, who would be truly external examiners, might prove to be practicable. This function is being capably performed by the National Board in several schools.

#### THE QUESTIONS

The good question, whether posed by inside or by outside examiners, should collectively cover information, skills and technics, and capacity for thought and expression. Referring to Jones again, it should be of the right degree of difficulty, should be pertinent to important phases of the subject, should challenge and stimulate the candidate, and should invite original

thought. It should consider adequate sampling of knowledge and should permit ample time for thought and expression, whether oral or written.

The examiner must set his questions with the most scrupulous care as to both the nature and the phrasing of the questions. Clarity is essential. Fairness is imperative. "Trick" questions are inexcusable. Hobbies must be avoided. Questions not germane to the field covered serve to confuse the candidate. The purpose of the examination is to determine professional qualifications, and any departure from that principle avoids the main issue. It is suggested in passing that, while questions on the history of the subject may give a clue to the cultural attainment of the student, they are of no value in estimating his scientific equipment. The examiner must be especially precise in his use of the words discuss, explain, outline, name and define. They all are explicit directions to the candidate and should be considered as such in grading the answers. Technical terms are employed for the sake of brevity, but they should be limited to what might properly be considered as within the student's province at the particular period of his career. The protest against the use of proper names in technical terms is a fetish that can be much overworked. Judgment must be exercised as to what terms may properly be employed, based on the student's presumed familiarity with them. It is ridiculous to direct a student to "read all questions carefully" unless they are written carefully.

#### THE EXAMINEE

The candidate has his own part to play in the success of the examination. He must not regard the examiner "as a deadly foe, whose very worst is to be expected," but rather as a more or less abstract figure whose sole interest is to determine without prejudice the student's fitness to pass. As is usual and proper, the examination has a time limit. The written examination should have a spatial limit. Proper familiarity with the subject or subjects should enable the student to give his answers within the prescribed limits of time and space. If the student is given the liberty of a selection of the questions he is to answer, he should choose those to which he can give the best answers as distinguished from those about which he thinks he knows most. In other words, he should study the nature of the directions, because, for example, he may be able to explain something better than he can discuss something else, even though he is more familiar with the topic covered by the latter. After the selection, the student would do well to allocate the time available into appropriate periods for each question. This allocation is to be determined by the time required for thinking over, organizing and writing each answer rather than by allotment of the same amount of time for each. He must do the same for space if that also is limited. He is forced to assume that the questions are carefully worded, even although at times this may strain his credulity. If he is directed to discuss a subject, the discussion should follow a clear plan of definition, nature, causes, effects, manifestations, treatment or prevention such as the problem may require. If he is directed to define, he is not required to, and indeed should not, discuss. If directed to give a brief answer, it should not be a diffuse answer. He should expect the examiner to grade him on the exact requirements of the question, and the examiner who does not do so is derelict in his duty. All too often the student interprets such directions as discuss, outline or define to

# HOSPITAL SERVICE IN THE UNITED STATES

SIXTEENTH ANNUAL PRESENTATION OF HOSPITAL DATA BY THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS OF THE AMERICAN MEDICAL ASSOCIATION

1. Report on Annual Census of Hospitals. 2. Comment on Internship. 3. Approved Schools for Technicians. 4. Hospital Medical Library Suggestions. 5. List of Registered Hospitals.

The largest number of beds in hospitals, and the largest number of patients admitted—as well as the greatest average census in hospitals—were among the all-time records established by the Annual Census of Hospitals just completed by the Council on Medical Education and Hospitals of the American Medical Association.

The admissions numbered 8,646,885, being 929,731 more than the preceding year.

The number of babies born in hospitals reached 831,500, an excess of 69,152 over the preceding year.

The number of beds, not including bassinets, has mounted to 1,096,721, as compared with the previous year's 1,075,139.

1936, a drop of 11,424. General hospitals had 144,880 empty beds in 1935 and 130,947 in 1936.

The facts cited are significant evidence of the increasing use of hospitals as centers of medical practice.

## A RECORD RESPONSE

Credit for the completeness of the census, making such a mass of useful facts available in so short a time, is due, in a large part, to the persons in charge of hospitals who, by their understanding and cooperation, rendered such prompt and carefully prepared returns.

The total number of registered hospitals now is 6,189, and the Council's special census questionnaire was answered by 5,989 of these, a record of 97 per cent. In this also the hospitals exceeded their own fine records of previous years.

## OVERCROWDING IN STATE MENTAL HOSPITALS

AS SHOWN BY EXCESS OF AVERAGE DAILY CENSUS OVER RATED CAPACITY

Number of institutions with no excess of daily census over rated capacity.....	93
Number of institutions with less than 15% excess.....	61
Number of institutions with 15-30% excess.....	46
Number of institutions with 30-50% excess.....	24
Number of institutions over 50% excess.....	4
Number of institutions not reporting both rated capacity and daily average census	19
Total.....	247

In some of the better institutions a daily census which does not exceed the rated capacity by more than 15 per cent may not be serious, but there are evidently 74 institutions (4 + 24 + 46) in which the patients exceed the capacity by more than 15 per cent. Conditions with reference to overcrowding are shown by states and by individual hospitals in later parts of this article.

There are 4,384 hospitals that have their own laboratories, and x-ray departments were reported by 4,733 hospitals.

There was a net increase of 21,582 beds over last year's census, this being the twenty-seventh year in which a similar increase has taken place.

Using the population estimated as of July 1, 1936, by the United States Bureau of the Census, one person in fifteen became a hospital bed patient during the year.

The 4,207 general hospitals admitted 7,755,848 patients, or 89.69 per cent of the 8,646,885 patients admitted to all hospitals. The total patient days in general hospitals was 99,426,828, or 29.9 per cent of 332,516,856 patient days in all hospitals.

The average length of stay per patient in general hospitals was 13 days.

In the foregoing paragraphs and throughout this article the figures for "patients admitted" and "average daily census of patients" are exclusive of new-born infants and do not include outpatients.

The average number of empty beds in 1935 was 199,629 for all hospitals, as compared with 188,205 in

All but two of the 939 hospitals that are approved for internships and residencies answered the questionnaire. The figures that they supplied were for the calendar year 1936. All other hospitals supplied figures for a period ended Sept. 30, 1936, or their latest fiscal year. Present conditions do not permit of exactly the same fiscal year for all hospitals. The present census, however, covers very nearly the calendar year 1936.

The 200 hospitals that did not respond to this census are nearly all small institutions, so that the response based on number of beds would amount to better than 99.5 per cent. Even those that did not respond in this census had for the most part submitted data within a few months previously. The first complete census was taken in 1909, twenty-seven years ago. The census has been made annually by the Council since 1920.

## GROWTH OF HOSPITALS

For indication of trends in the hospital field, special reference is made to tables 1 and 2, which present a summary of the entire census for the year 1936, classifying hospitals first as to ownership or control and

mean "tell all you know about." This is a degradation of the examination and should be so interpreted by the examiner. It is an imposition on the time and good nature of an examiner to expect him to peruse a large volume of material, more or less illegible, in order to glean a few statements directed to the point under consideration. The just examiner grades on the basis of specific answers to specific questions rather than on the basis of the number of words employed. He cannot be blamed if he becomes impatient at diffusion and indirection. He is often possessed of a sense of humor, but it is likely to be sadly warped by attempts to evade an issue. The student also may boast of his humor, but an examination paper is a poor place for its exhibition.<sup>4</sup> The examination of medical students is deeply serious, for it is one of the critical items in the preparation of students for graduation, for the maintenance of the good name of a school and for the protection of the public.

As Murrell puts it, "to the discerning eye nothing is more fascinating than the way in which the mind advances from weakness to power, from vagueness to precision, from halting clumsiness to refined accuracy, from the limited to the embracing point of view." To the teacher in the medical school there is the added pleasure of witnessing advancing earnestness of work, improving deftness of technic, growing objectivity in the study of disease, increasing gentleness at the bedside, expanding sympathy with human frailty and enlarging appreciation of the nobility of a career of service. One of the teacher's great joys is to be found when, during and at the end of the medical school apprenticeship, the student passes an examination with credit to his instruction and satisfaction to himself.

#### EPICRISIS

A thoughtful consideration of examinations has led to the formulation of an opinion that they should constitute an integral part of a well planned program of instruction; that the comprehensive examination offers the advantages of deferred review, the covering of marginal fields and the determination of relational thinking; that the decision as to types of examination shall be reached only after careful survey of all the forms; that the examiner has serious duties in posing questions, in grading and in determination of the relative weight of written and oral examinations, and that the examinee must appreciate the importance and significance of the examination in his professional career. Education is favored by acceptance of examinations as a major function of the teaching staff.

4. Stephen Leacock intimates that the candidate can take it for granted that the examiner is a conceited, pedantic person, and that "much can be done by sheer illegibility of handwriting, by smearing ink all over the paper and then crumpling it up into a ball." Examiners in the medical schools have it within their power to annihilate this attractive (or, in the mode of the day, intriguing) hypothesis.

**An Attribute One Cannot Estimate.**—Devotion is an attribute one cannot estimate and record by ordinary standards. How much the practicing doctor cares about his patients as individuals apart from their being the source of his livelihood; how much the medical scientist may be interested in promoting science rather than in securing his own promotion; how much the teacher influences his pupils to their best efforts, unmindful of what the curriculum briefly requires of him; how much the student engages in his work for the work's sake, regardless of his marks and rating—all these things depend on a devotion which places spiritual above material rewards.—Cushing, Harvey: *Consecratio Medici and Other Papers*, Boston, Little, Brown & Co., 1928.

## THE MEDICAL SCHOOL SURVEY

HERMAN G. WEISKOTTEN, M.D.  
Dean, Syracuse University College of Medicine  
SYRACUSE, N. Y.

My first public utterance in connection with the survey of the medical colleges of this country cannot be other than a tribute to the thousands of practitioners of medicine who, without any financial remuneration, are contributing so unselfishly of their time and effort to the cause of medical education. Even in instances in which the facilities and end results leave much to be desired, the spirit and the contributions of this group are none the less commendable. I know of no group, professional or otherwise, which is making a similar contribution in the field of education. At the same time I wish to express to the deans and faculty members of the medical colleges of the country my sincere appreciation of their cordial cooperation in the conduct of the survey.

I have been asked to present at this time some of my observations and immediate reactions to the survey. At the same time an opportunity is afforded to present some of the problems in the development of medical education which our study has thrown into relief.

#### PROCEDURE

In order that the basis for these observations and reactions may be better appreciated, I intend to outline briefly the technic followed in the conduct of the survey.

This enterprise was initiated and conducted by the Council on Medical Education and Hospitals of the American Medical Association with the cooperation of the Association of American Medical Colleges and the Federation of State Boards of Medical Examiners. It involved a study of all the medical colleges in the United States on the Council's list of approved medical colleges or in membership in the Association of American Medical Colleges and such others as would consent to being included. On their invitation, all the medical schools of Canada were included in the survey.

Some time before each college was visited, a set of questionnaires was sent to the dean with a request that they be filled out and returned to the office of the Council before the time of the visit. The set of questionnaires included the following:

A questionnaire on the organization and administration of the school, to be filled out by the dean.

A questionnaire requesting information with regard to clinical facilities and hospital relationships.

A questionnaire for each department in the school, including the library. These questionnaires called for information on departmental organization, staff, facilities, hours in the curriculum, methods of conducting courses, research, relationships with other departments, and budget. They also sought suggestions with respect to course content, teaching methods, and the place of the subject in the curriculum.

There was also provided a separate personal questionnaire for every member of the faculty of the rank of assistant professor and above. This called for an outline of training and experience, scientific society memberships, participation in scientific society programs, publications, proportion of time devoted to teaching and research, and participation in community programs related to the field of medicine.

Read before the Thirty-Third Annual Congress on Medical Education and Licensure, Chicago, Feb. 15, 1937.

second as to the type of service rendered. Summaries for each preceding year back to 1927 are given at the bottom of the tables, affording ready comparison.

A glance at the foot of table 2 shows that the number of hospitals decreased the past year from 6,246 to 6,189. Bassinets increased from 53,310 to 54,225. The average census increased in the same time from 875,510 to 908,516.

There was a decline in the number of general, nervous and mental, industrial, eye, ear, nose and throat, isolation and convalescent and rest hospitals. The only types of hospitals that increased in number were those for tuberculosis, maternity, children, orthopedic, and the hospital departments of institutions.

All groups of hospitals, as to type of service, have increased in patients admitted and average census, with the exception of industrial and convalescent and rest which have decreased in average census, and isolation hospitals which have decreased in the number of patients admitted as well as the average daily census. Maternity hospitals, children's and hospital departments of institutions increased in beds, bassinets, number of patients and average census.

The total patient days in all hospitals was 332,516,856. This is obtained by multiplying the average census of hospitals by 366, the number of days in the year.

This means that patients came to hospitals at the rate of sixteen for every minute in the year, including Sundays, holidays, day and night.

Growth of hospital facilities for the last twenty-seven years has been at an average of 25,024 beds a year. This is the equivalent of a net increase of 68 beds for every day in the twenty-seven years.

Summary of Growth of Hospitals, 1909 to 1936

	Federal Hospitals		State Hospitals		All other Hospitals		Total	
	Num-ber	Capac-ity	Num-ber	Capac-ity	Num-ber	Capac-ity	Num-ber	Capac-ity
1909...	71	8,827	232	189,049	4,056	223,189	4,359	421,065
1914...	93	12,602	291	232,834	4,650	287,045	5,037	532,481
1918...	110	18,815	303	262,254	4,910	331,182	5,323	612,251
1923...	220	53,569	601	302,208	6,009	309,645	6,830	755,722
1928...	294	61,765	595	369,759	5,963	461,410	6,852	892,934
1931...	291	69,170	576	419,252	5,746	485,663	6,613	974,115
1932...	301	74,151	568	442,601	5,693	497,602	6,562	1,014,354
1933...	295	73,635	557	459,646	5,585	491,765	6,437	1,027,046
1934...	313	77,865	544	473,035	5,477	497,201	6,334	1,048,101
1935...	316	83,353	526	483,994	5,404	507,792	6,246	1,075,139
1936...	323	84,234	524	503,306	5,342	509,181	6,189	1,096,721

The 6,189 registered hospitals may be thought of in two main groups: first, the registered hospitals and sanatoriums that are approved for the training of interns and resident physicians, and the second, hospitals, sanatoriums and related institutions registered but not so approved. The following table explains this grouping and gives the basic figures as to capacity and patients admitted in each group:

	Number	Beds	Bassinets	Patients Admitted in 1936
1. Registered hospitals and sanatoriums approved for training interns and residents .....	939	369,478	24,112	4,596,453
2. Other hospitals, sanatoriums and related institutions, registered .....	5,250	727,243	30,113	4,050,432
Total registered .....	6,189	1,096,721	54,225	8,646,885
3. Refused registration after investigation .....	581	17,193	1,873	

The hospitals approved for internships and residents cared for more than half of the patients admitted to all hospitals in the year 1936. Thus for the first time more than half the patients in the hospitals of the country were in hospitals approved for the formal education of physicians.

Of the 5,250 hospitals, sanatoriums and related institutions registered but not approved, approximately 1,638 are approved as meeting the minimum standards of the American College of Surgeons. The College, of course, approves practically all those that the Council approves

for intern training and residencies. Standards used by the College and the Council are similar in many respects, one essential difference being the Council's emphasis on the educational program for the internship, or fifth year in medicine, and for residencies in specialties. There still remain 3,612 registered hospitals that, so far as we can learn, meet the requirements for registration but which have not as yet been brought up to the standards either for the training of interns or resident physicians or for meeting the minimum requirements of the College.

There is, therefore, much work to be done in the further improvement of hospitals that are registered.

In addition to the foregoing there are 581 hospitals that, after investigation, have been refused registration.

Further still, there are certain types of small institutions, first aid and emergency stations, makeshift places of small capacity, nondescript and emergency services, to the number of 1,989, which, of course, have not been considered for registration as hospitals.

#### HOSPITALS ACCORDING TO CONTROL OR OWNERSHIP

Hospitals may be classified according to control or ownership into three major groups corresponding with the sections of table 1:

- Governmental
- Nonprofit Organizations
- Proprietary

Government hospitals include those run by the federal, state, county, and city governments. The total number of governmental hospitals is exactly the same as one year ago, 1,724, but there has been a rather large increase both in the capacity and in the occupancy of the governmental group. The federal hospitals, for example, increased from 316 to 323 and show a considerable growth in the number of beds, bassinets, patients admitted and average census.

The questionnaires were usually not examined before the school was visited. This was thought to be the more reasonable procedure, enabling those visiting the school to get a more objective picture of it, uninfluenced by any statements included in the questionnaires. However, all the questionnaires were carefully studied before an evaluation of the school was made and before a report on the visit was made to the school.

In visiting the school I was in each instance accompanied by a representative of the Association of American Medical Colleges, of the Federation of State Boards of Medical Examiners or of the Council on Medical Education and Hospitals of the American Medical Association.

Three days was spent at each school. The procedure was as follows: From one to three hours was devoted to an interview with the dean of the school. During this time the visitors endeavored to reach a fair understanding of the organization and conduct of the school, its policies of admission and promotion, its affiliations and relationships to other schools and departments of the university, its clinical facilities, and its programs for development. The dean was also requested to furnish a financial statement on a form provided by the Council.

Following the interview with the dean, approximately one hour was devoted to an interview with the head of each of the major departments of the school. An attempt was made to get a clear picture of the departmental organization, the curriculum as related to the department, the course content, methods of teaching, relationships to other departments, and additional responsibilities of the department and its staff. The department quarters and equipment were seen at the completion of the interview.

Wherever possible, the departments were visited in the order of their sequence in the curriculum so that the visitors during the three days might "take the curriculum" by progressively building up a picture of the courses as offered with all their correlations and implications.

Although questionnaires were filled out by the heads of all departments, as a rule the activities of the specialty departments were not covered in any detail at the time the schools were visited except so far as phases of the specialties were included in the teaching of the major subjects. There were several reasons for this. In the first place, the program called for covering all the schools within a period of two years. There is also a question in the minds of many medical educators as to how much of the specialties should be included in the undergraduate curriculum. Further, several of the national specialty groups have made rather comprehensive studies of the teaching of their specialties in the medical schools of the country.

During all the interviews I made careful and detailed memoranda. Based on these memoranda, rather full detailed notes of the day's visits were dictated every evening.

At the end of the third day my covisitor and I conferred and dictated a summary and impressions. These became a part of the detailed notes on the visit and were signed by both.

Sometime during the visit the president of the university and, in certain instances, members of the board of trustees were interviewed. These interviews dealt with the attitude of the university toward the medical school and medical education, the possibilities of continued or more adequate support, programs for develop-

ments, and any situations that might affect the present or future status of the school.

All data dealing with the survey, including the questionnaires, the notes on the visits and, in many instances, laboratory outlines and other literature dealing with the conduct of courses were filed in the office of the Council on Medical Education and Hospitals.

Subsequent to the visits to the schools, there were prepared abstract reports on some of the schools. These were based on a study of the questionnaires, the notes dictated at the time the schools were visited, the official publications of the schools, and the financial statements submitted by the deans. These abstract reports were submitted to the members of the Council on Medical Education and Hospitals, after which they were sent to the respective schools. Up to the present time about forty such reports have been prepared and sent out.

#### PERSONAL REACTIONS

Comprehensive as our procedure in the conduct of the survey may appear, it was recognized from the very beginning that it left much to be desired. Certainly three days is inadequate time in which to learn all about any school. However, certain fundamental facts could be definitely determined.

In the brief time available, I can hope to do no more than give a sketchy outline of my personal reactions to the survey.

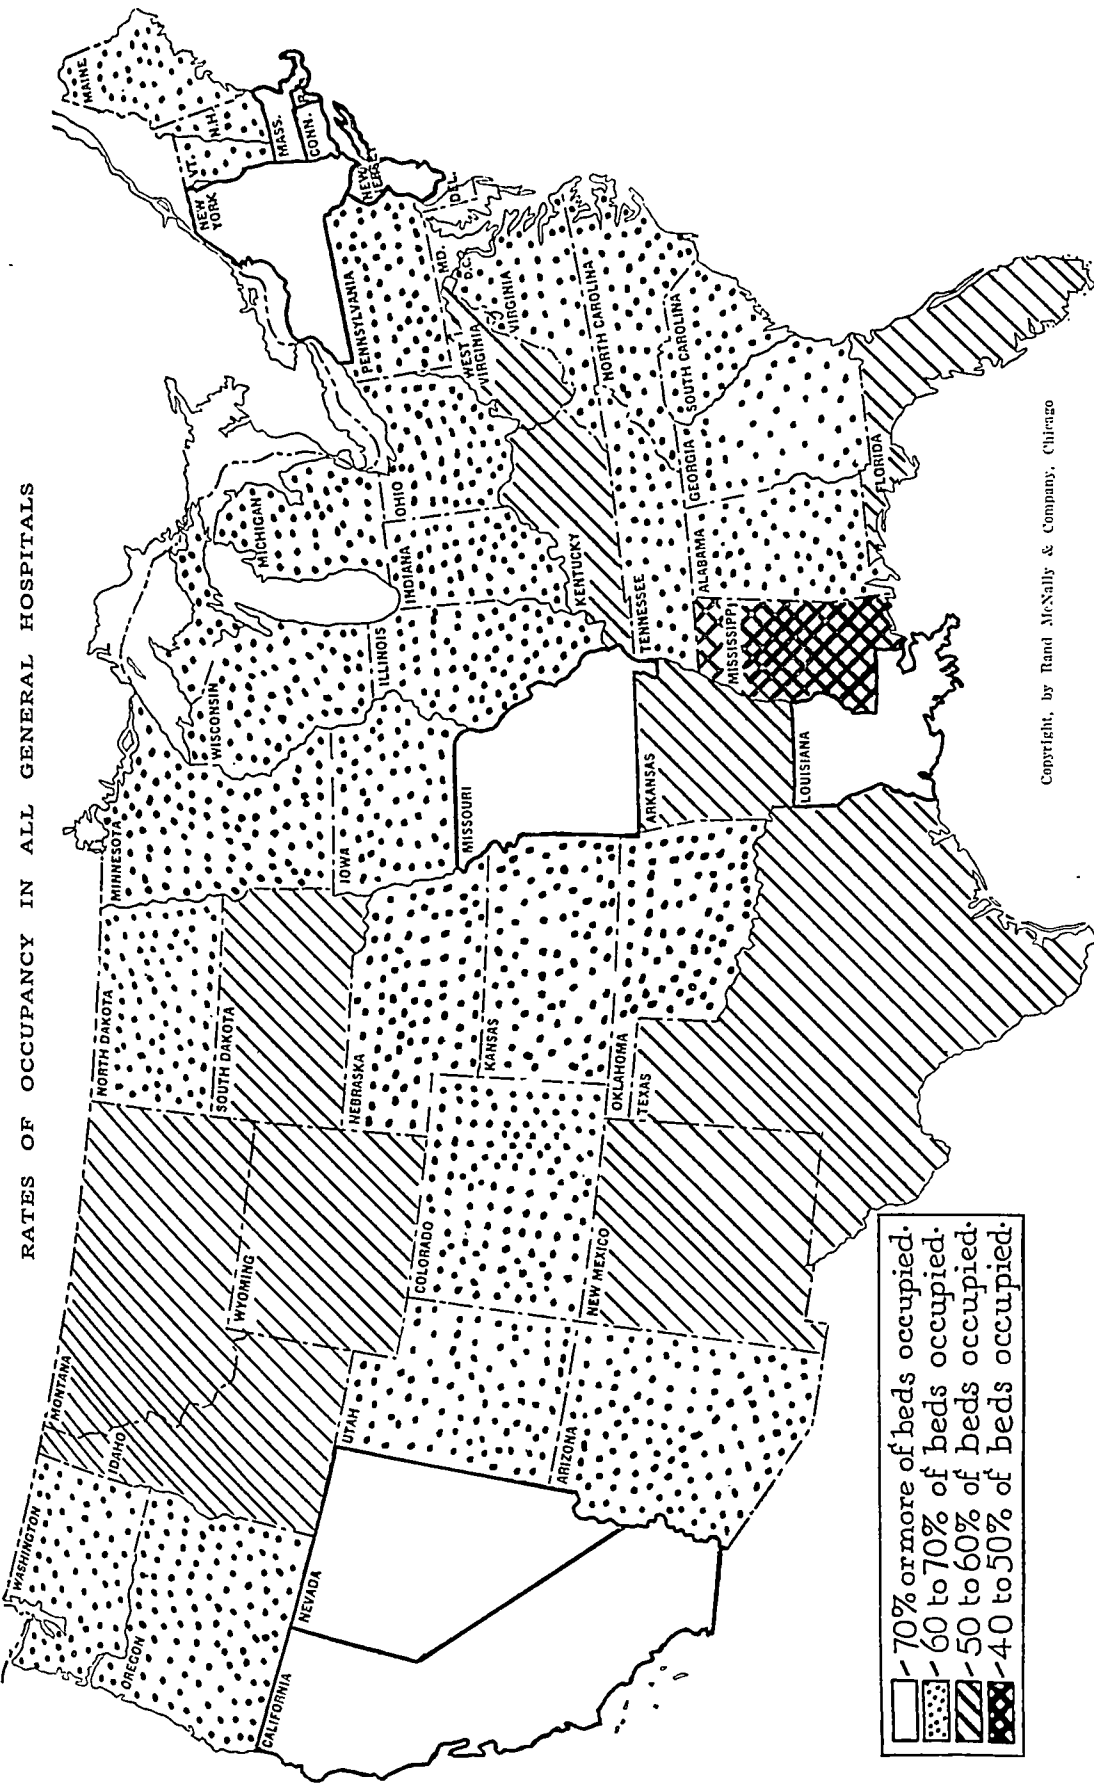

My first reaction was, I am sure, a perfectly normal one. The more experience I had in studying the details of medical education, the less I knew about them. During the early part of the survey a mass of complicated, apparently uncorrelated details seemed to present a rather confusing picture. However, as the survey progressed there began to evolve certain fundamental principles which were recognized as essential to a satisfactory undergraduate course in medicine. In fact, I believe that these fundamental principles are in no way peculiar to medical education.

It is some of these fundamentals which I wish to discuss briefly. At one of these meetings a few years ago, Dr. Alan Gregg made the statement that a university is an aggregation of scholars. This suggests the dominant importance of the faculty in organized education. The recognition of scholars and the evaluation of faculty members is not always easy. However, realizing all the difficulties involved, it would appear that in many instances far too little attention has been given to the selection of the faculty. It is safe to assume that a teacher should have some special preparation and that an individual who has had no such training or experience in a subject is not competent to teach it.

The use of student assistants as responsible teachers presents many problems. In certain instances such student assistants who have only just completed a course are assuming major teaching responsibilities in connection with it. Some of these student assistants are carrying a full schedule of school work. Others are on a part-time basis, and others have discontinued their medical college course for a year to become student assistants and earn a master's degree. Regardless of the value of such student assistantships to the student assistants, one may well question the justification of using these students to supplement entirely inadequate department staffs. Under such circumstances it usually develops that both students and student assistants receive inadequate supervision and guidance in their work.

RATES OF OCCUPANCY IN ALL GENERAL HOSPITALS

Copyright, by Rand McNally & Company, Chicago

Occupancy in General Hospitals

The percentages of beds occupied in general hospitals during the year 1936, by states, were as follows:

Alabama.....	64.6	New Jersey.....	71.4	Oregon.....	69.7
Arizona.....	65.3	New Mexico.....	59.3	Pennsylvania.....	68.6
Arkansas.....	72.8	New York.....	75.0	Rhode Island.....	64.2
California.....	70.4	North Carolina.....	64.3	South Carolina.....	61.7
Colorado.....	61.3	North Dakota.....	66.5	South Dakota.....	61.7
Connecticut.....	71.3	Ohio.....	67.0	Tennessee.....	64.4
Delaware.....	66.9	Oklahoma.....	62.3	Texas.....	65.7
District of Columbia.....	80.1	Minnesota.....	68.3	Utah.....	64.6
Florida.....	58.0	Mississippi.....	45.4	Vermont.....	64.2
Georgia.....	61.6	Missouri.....	70.9	Virginia.....	61.7
Idaho.....	59.7	Montana.....	63.7	West Virginia.....	65.5
Illinois.....	63.0	Nebraska.....	63.6	Wisconsin.....	65.1
Indiana.....	63.5	Nevada.....	73.1	Wyoming.....	69.0
Iowa.....	61.3	New Hampshire.....	62.5		
Kansas.....	80.1				
Kentucky.....	58.0				
Louisiana.....	61.6				
Maine.....	59.7				
Maryland.....	63.0				
Massachusetts.....	63.5				
Michigan.....	61.3				

Degrees are frequently used in the evaluation of university faculties. However, one finds, for example, a faculty member who has earned, or at least received, an A.B., a Ph.D. and an M.D. degree within a period of four years and has served as an instructor during three of these years. At the same time the medical school granting the M.D. degree is one requiring the fifth or intern year. Such situations make one place little weight on degrees alone. The mere fact that a man has acquired an advanced degree in anatomy, physiology or any other subject by no means makes him an acceptable or competent teacher in a medical school.

It is apparently true that at the present time there is a shortage of well trained, competent teachers, especially in the preclinical departments. The opportunities offered in connection with full-time positions in the clinical departments have apparently proved to be more attractive to medical graduates trained in chemistry, physiology, bacteriology or pathology than have similar positions in the preclinical departments. It is of the greatest importance to see to it that satisfactory and attractive opportunities are offered for careers in all departments of the medical schools if this situation is to be improved.

Another fundamental principle involves a clear recognition of the objectives to be attained in connection with the undergraduate course. Certainly the published statement of objectives in a catalogue is no guaranty of a school's excellence or of the attainment of the objectives published.

The objectives of different schools may, and perhaps should, vary in certain respects, but all should include such basic training as is essential to all fields of medicine. This basic training is usually recognized to include the acquiring of a knowledge of the fundamentals of the medical sciences, the acquiring and understanding of certain fundamental technics, the development of initiative and the development of a scientific point of view and of proper methods of work. Only with such a foundation is a student prepared to continue his education after graduation as is essential to a successful career in medicine.

Each department in the school must appreciate the part it must play in the attainment of these objectives, and the entire undergraduate curriculum should be a coordinated whole directed toward these ends.

The continued visualization of objectives and the conduct of a well coordinated program directed toward their attainment requires frequent departmental, inter-departmental and faculty meetings. It is my impression that the schools which have the greatest need for such meetings are those in which the fewest are held. Through lack of such meetings a school frequently fails to profit by the presence on its faculty of one or more outstanding educators who are never given an opportunity to influence the curriculum as a whole or even to become familiar with the work of departments other than their own.

As a result of lack of serious consideration of objectives, the curriculum is frequently set up to provide for so many hours of this or that subject to meet either stated requirements or recognized trends. The "willy-nilly" inclusion of a stated number of hours of psychiatry or so many hours of public health and preventive medicine contributes little, if any, to the training of the student.

Too many of the courses in some of our medical schools are still merely stereotyped textbook and

laboratory courses attempting to cover an impossible amount of material and contributing little or nothing to the intellectual development of the student. Kaleidoscopic superficial impressions are a detriment rather than a help in the development of a mind.

It would also appear to be important that there be a clearer understanding as to what should be involved in connection with certain recognized features of the undergraduate program. The mere designation of an element of the curriculum by a new and perhaps popular name means no advancement in development. There certainly is no magic in words. For example, every type of examination imaginable may masquerade under the popular designation "comprehensive examination." Similarly so-called clinical clerkships may involve merely ward walks and clinics or actual responsibility for the complete work-up of cases and the close following of their progress.

Too many of the preclinical courses are merely a mimicry of nonmedical university courses inflicted on the medical students by teachers whose sole experience has been a graduate course in a single subject which has been almost devoid of any of its medical implications. I do not for one moment wish to minimize the importance of pure science, but our undergraduate program calls primarily for the development of practitioners of medicine and involves the preparation of the student for his introduction to clinical medicine in his second or third year. Then, too, many of the fundamental principles of the medical sciences can be as well, if not better, taught in connection with human phenomena. Furthermore, the early appreciation of the medical implications of these principles as well as the early application of the various technics as applied to clinical medicine detract in no way from the scientific value of these courses. On the other hand they tend to emphasize a purposefulness which is stimulating to the student.

A few years ago we heard much of university departments in the field of medical education. Today it would appear that, at least in many instances, medical education is in conflict with efforts to diffuse the services of a department throughout a university. When such a university department staff is at one time responsible for teaching from seven hundred to more than a thousand students from several different divisions of the university, one wonders whether it is possible for the staff to give the desired amount of interest and attention to the developing of its medical students. Especially is this true when the medical students are taught in the same sections with students from other colleges of the university.

The undergraduate curriculum should be adapted to the fundamental and specific objectives of the particular school and will vary more or less according to these objectives. Unwarranted attempts at mimicry in curriculum layout have served as a definite handicap to the development of certain schools. The details of the curriculum programs must vary, depending on available faculty, physical and clinical facilities, and other local factors.

Further, it is important that in every school the curriculum should be planned for its average student. At the same time it should offer additional opportunities for the better students. This is a principle which is fortunately becoming rather generally recognized in the field of higher education.

At this point I would stress the importance of the curriculum providing opportunity for an intimate

State hospitals lost two as to number but increased in bed capacity, number of patients admitted and the average census.

County hospitals dropped from 490 to 484. There was a decrease in the number of beds and in the aver-

#### NONPROFIT ORGANIZATIONS

This large and important group, responsible for a majority of the general hospitals, now numbers 2,711 hospitals as compared with 2,640 a year ago. The number of beds has increased from 268,568 to 275,874. Bassinets have also increased. The number of patients admitted has come up from 4,477,515 to 5,258,772. The average census has increased from 167,680 to 181,547.

The number of church hospitals, and their capacity in beds and bassinets, has remained practically stationary for the year, but they have enjoyed an increase in patients admitted from 1,950,308 to 2,286,064. The average census of church hospitals has increased from 69,592 to 74,037.

Fraternal hospitals have continued their downward slide from 69 to 64 in number and a corresponding marked decrease in all other figures relating to capacity and occupancy.

The independent nonprofit corporations and associations are those concerns that have been organized for the express purpose of operating hospitals. They have to their credit a very substantial increase in capacity and occupancy during the past year, having grown in number from 1,601 to 1,678. The capacity has increased from 149,940 beds to 157,650 beds and from 19,978 bassinets to 21,122, and the number of patients admitted from 2,493,281 to 2,939,651. The average census of their patients has increased from 94,468 to 104,169.

#### PROPRIETARY ORGANIZATIONS

The third group of nongovernmental hospitals, the proprietary institutions, exhibited a rather slight decrease in all figures relating to capacity and occupancy. Shrinking in number from 1,882 to 1,754, they declined likewise in capacity from 64,859 to 57,007. Bassinets were reduced from 8,741 to 7,985; patients admitted from 946,587 to 935,254, and the average census from 32,909 to 30,134.

The individual and partnership hospitals numbered 1,255 a year ago as compared with 1,204 at the present time. There has been a similar decline in the number of beds, bassinets and average census, although a slight increase in the number of patients admitted.

The corporations unrestricted as to profit are the ones most frequently referred to as "incorporated for profit." In this group the decline in all of the capacity and occupancy figures is rather spectacular. There was a slide in the number from 627 to 550; in bed capacity

teacher-student relationship. It is only in connection with such intimate relationships that the student will acquire the stimulus, the scientific point of view and the methods of work that are essential to his successful development. Most of the outstanding men in the field of medicine with whom I have talked definitely attribute their success to such intimate association with some one or more of their teachers.

This suggests a word with regard to the most important factor in the whole field of medical education—the student. The importance of careful selection is receiving much attention and cannot be overemphasized. Too many schools are still admitting obviously unpromising and poorly prepared students. Some of these are being admitted on the basis of graduation from junior colleges. The formal and rigid premedical college course has also, I believe, been a definite handicap in the development of medical education. Unfortunate indeed is the medical school which feels compelled to accept all applicants from within its district who meet the minimum credit hour requirements for admission.

I believe that it should be more generally recognized that no educational institution can make a good mind out of a poor one. It may in certain instances give it an artificial veneer, which may mislead both the student and the public. At the same time it is fortunate that no educational institution can ruin a good mind. It may handicap it in its development but ruin it, it cannot.

It not infrequently happens that a school points with pride to the achievements of some one or more of its graduates when as a matter of fact these graduates achieved success in spite of rather than because of their experiences in the school.

There are a considerable number of other problems in medical education which deserve thoughtful consideration. I can do no more than mention some of these at this time, hoping that in connection with a further study of the survey data they may receive the attention which they deserve.

The essential elements of sound organization and a control that will guarantee the independence of the school from political or other undesirable influences is a subject that requires study and frank discussion.

Provision for an effective educational administration is also essential to the satisfactory conduct and development of a school.

The problem of the size of the student body as related to educational standards, physical facilities, departmental staffs, kind and amount of clinical facilities and the public need deserve careful consideration.

The complete availability of an adequate number of clinical cases, sufficiently diverse as to disease type and available, moreover, under conditions which permit a high standard of training and experience for the student is one of the greatest problems facing most of the schools of the country.

The responsibility of the college in connection with internships is a problem of fundamental importance regardless of the requirement of the intern year for the M.D. degree.

Beyond this is the relatively enormous problem of graduate work in medicine. There are today programs leading to graduate degrees based solely on an internship with perhaps, in addition, a thesis requirement. The increasing standards demanded in the training of specialists forces us to a serious study of available opportunities and standards in this field.

Closely related to this is the question of simultaneous registration in the medical school and graduate school and the application of medical school credits toward a graduate degree.

One gets the impression that the whole field of graduate study must be given early and thorough attention.

The presentation and discussion of such problems as I have mentioned should not be misinterpreted and should be in no way discouraging.

Probably no group of educators have within recent years effected advances comparable to those in the field of medical education.

As has been pointed out by our chairman, Dr. Ray Lyman Wilbur, one of the reasons that many of us have not made the progress we would desire is that financial support has been entirely inadequate.

The universities and the public must realize that medical education is expensive. However, the development of a competent personnel to assume the responsibilities incident to the prevention and treatment of disease and the advancement of medical science fully justifies much more adequate support than is now being given to the medical colleges of this country.

---

## HOW MANY HOSPITAL BEDS ARE ENOUGH?

CHARLES F. NEERGAARD

Hospital Consultant

NEW YORK

It has long been obvious to those who take time to view the hospital field in perspective that there are too many hospital beds for acute cases. It is rather a startling fact when one stops to think of it that on the average day the general hospitals of the country are carrying fifty or more empty beds for every hundred occupied. This has not been generally realized in medical and hospital circles; its significance in terms of money has not been understood.

This study is an attempt to discover what bed capacity is actually needed to accommodate the daily toll of acutely sick and injured, and to determine "how much is enough" for reserve.

A report published by the American Hospital Association<sup>1</sup> dealing with overhospitalization advanced the theory that three beds for every two patients was too many and that it should be possible for the general hospital, given a flexible building and less rigid policies in the grouping of patients, to handle its work effectively with five beds for every four patients, or a reserve of 25 per cent instead of 50 per cent. It found that 4,000 general hospitals reporting in 1934 to the American Medical Association had 87,500 beds in excess of such 25 per cent reserve and estimated that this surplus had cost the public in fixed charges \$61,250,000—a sum sufficient to have paid for the care of nearly a fifth of all the patients whom the hospitals had treated that year.

Surely the most wasteful thing in a hospital is a bed that is never needed.

Idle beds are a heavy charge on institutions already suffering from a crushing load of charity work. This is of particular importance in view of the clear indications that hospital construction is being resumed on an increasing scale. The *Modern Hospital* reports 578 building projects last year aggregating nearly

\$100,000,000. From coast to coast medical staffs are urging the need for new hospitals or the expansion and modernization of old ones. Before the hospital field embarks on a new era of construction or reconstruction based on hazy or incomplete knowledge, an effort should be made to determine some method of appraisal that will indicate in any given situation or

\* This study was made possible by the courtesy of the twenty-four hospital superintendents who opened their census records to the author.

locality how many beds are actually needed to cover a reasonable reserve for peak loads. Construction programs beyond that point are wasteful and unsound, a handicap to management and an inexcusable drain on the all too limited funds available for health and philanthropic purposes.

This study has been made with a view of throwing some light on the peak load.

I have sought to prove a theory: that a general hospital should be able to handle its work if it has one reserve bed for every four patients in its average daily census. The accompanying tables indicate the days of overcrowding that would have occurred in forty-five hospital years if these hospitals had carried only a 25 per cent reserve. The study is based on the number of patients which they treated irrespective of the number of beds which they had. The days of peak load are figured at 120 per cent of the average census for the year (when 98 per cent of the beds, given a 25 per cent reserve, would have been occupied) and the maximum at 125 per cent when every bed would have been filled and perhaps a few extra beds set up in solariums.

The outstanding facts which these tables disclose are that in the forty-five years of hospital experience there was an average of but 17.4 days a year of peak loads, of which but seven days found the hospital full to overflowing.

The daily census records of twenty-four hospitals for the years 1934-1936 were reviewed in detail. While this is but a minute fraction of the total field, the hospitals in question, mainly voluntary general, have a total capacity of nearly 10,000 beds and are scattered from Maine to California in cities, towns and suburban districts and are a fair cross-section of the whole. While the sampling is too small to warrant definite conclusions, many interesting and significant facts emerge. It is hoped that the picture presented will stimulate some organized research of broader scope from which may come the more precise formulas so sorely needed for determining hospital requirements.

#### SIGNIFICANT FACTS SHOWN BY ANALYSIS OF TABLE 1

1. Hospitals that operate at relatively high average capacity have fewer days of high census (table 2).

2. The hospitals of smaller capacity experience wider fluctuation than the larger (table 3).

3. Peaks occur in every month of the year but are most prevalent in March, April and May. The work sheets for twelve hospitals, in which the census was taken off in detail by months for twenty-three hospital years, show the results given in table 4.

4. The number of days on which hospitals are crowded are relatively few in comparison with the large portion of reserve beds carried, as evidenced by the figures given in table 5.

These figures bring us back to the surprising disclosure that the occupancy statistics show peak loads on an average of 17.4 days, or less than 5 per cent of the year. Even more worthy of note is the fact that in

TABLE 2.—Census in Hospitals Operating at Relatively High Average Capacity

No. of Years	Occupancy of Beds	Number of Days When the Average Patients' Census Was Exceeded			
		By 20%	Average	By 25%	Average
13	in hospitals ranging from 71 to 100%	110	8.5	39	3
23	in hospitals ranging from 55 to 68%	370	16.5	168	7.3
9	in hospitals ranging from 46 to 54%	204	31.6	103	12
45 Total.....		783	17.4	315	7

TABLE 3.—Fluctuations in Hospitals of Smaller Capacity

No. of Years	Average Daily Census	Average Number of Days per Year When Census Reached or Exceeded	
		120%	125%
12	300 to 3,000	6.5	1.1
7	200 to 299	11.7	2.9
14	100 to 199	12.4	4.7
12	Up to 99	37.4	18
45			

twenty-three hospitals, or half of the total, the peak loads occurred on ten days or less. This would indicate that for at least 355 out of 365 days the excess or reserve beds are rarely if ever used.

I am conscious that there are many factors which might qualify these conclusions and that any observations to be conclusive should be based on far more comprehensive data and subject to a much more detailed analysis. These statistics are confined to postdepression years and further study should extend to depres-

from 34,946 to 28,511; bassinets from 4,357 to 3,629, and the patients admitted from 532,590 to 497,457; the average census declined from 18,697 to 16,462.

The total nongovernmental hospitals declined in number from 4,522 to 4,465, and in capacity from 333,427 beds to 332,881 beds. These hospitals, however, did increase in the number of bassinets, from 44,893 to 45,583. They increased also in the number of patients admitted, from 5,424,102 to 6,194,026, and the average census from 200,589 to 211,681.

given in the list of hospitals on following pages. The results are summarized in the first table on page 1044.

It would appear that the difference between the rated capacity and the average census of patients would, in a general way, tell whether or not there is overcrowding. The percentages on which the table was based were determined by taking the excess of the census over the rated capacity and dividing it by the rated capacity.

A tendency to overcrowd seems to be general, if not chronic, in state mental institutions. This is the reason

Tables 1 and 2 record conditions as of Dec. 31, 1936. Discrepancies between these figures and those found in the list beginning on page 1060 are due to the fact that the list was revised to March 15, 1937.

## OVERCROWDING IN STATE NERVOUS AND MENTAL

the cortex removed, was still driving a car. He wondered how this situation could be controlled and he was advised to tell the patient that he would get in touch with the police if he continued to drive. The patient had not realized how serious his offense was until it was brought to his attention by his physician, and it is my understanding that the patient immediately passed over the handling of his car to his wife and withdrew from active participation in it.

#### CONCLUSION

The public health field and the medical field of traffic accident prevention, through the intelligent use of medical diagnostic and treatment facilities in general, is relatively unexplored but already presents itself as a legitimate and sensible field for medical interest.

330 Recorder's Court.

### A PHARMACOLOGIC STUDY OF THE TOXEMIA THEORY OF SUR- GICAL SHOCK

CARL A. DRAGSTEDT, M.D., PH.D.  
AND  
FRANKLIN B. MEAD, S.B., M.S.  
CHICAGO

We<sup>1</sup> have elsewhere reported evidence indicating that, in the dog at least, the vasomotor symptoms and death occurring in anaphylactic shock are brought about by the sudden discharge into the circulating blood of a vasodepressor, smooth muscle stimulating substance which is apparently histamine. We have been able to detect this substance in the blood and thoracic duct lymph for brief periods of time after the assaulting or shocking dose of serum and have been able to correlate its appearance with the varying grades of severity of the shock in such a way as to indicate that it has a causal relationship to the shock symptoms.

Since the vasomotor phenomena of surgical shock have likewise been attributed to the absorption from the traumatized area of a vasodepressor substance such as histamine, the question arose as to whether a similar investigation would yield positive or negative evidence for such a toxemia theory. We are not here concerned with reviewing the extensive literature on the toxemia theory of surgical shock. Suffice it to say that both the proponents and the opponents of this theory have been chiefly concerned with detailed comparisons between the phenomena of surgical shock and those of a toxemia shock such as produced by histamine, with circumstantial evidence bearing on the question of a toxemia pathogenesis of surgical shock or with evidences that other than toxemia mechanisms are or are not adequate explanations of the shock phenomena. So far as we are aware, the only report in the literature concerned with a somewhat direct search for the hypo-

thetical toxin is the one by Phemister,<sup>2</sup> in which negative results were obtained when blood from the traumatized leg of one dog was collected in a viviparous flask and introduced into the circulation of a second animal without vasodilator effects.

#### METHODS

Dogs were used. They were anesthetized with ether and sodium barbital. Blood pressure records were made from the carotid, and the thoracic duct was cannulated for collection of lymph. Surgical shock was produced by sustained trauma with a padded hammer to one or both hind legs, by traumatizing the extruded intestine, or by a combination of these procedures. During the course of the ensuing shock, as gaged by the blood pressure record, samples of blood and of thoracic duct lymph were collected. These were kept from clotting by means of heparin in saline solution (freshly prepared) and were examined for the presence of physiologically active substances by testing on the isolated intestinal strip of the guinea-pig in the usual way, or by intravenous injection into an etherized, atropinized cat and noting the effect on the blood pressure. The bloods were centrifugated prior to testing and the respective plasma samples employed, while the lymph specimens were employed directly. Either of these test methods will readily detect histamine if it is present in the lymph or plasma in concentrations around 1:250,000.

#### RESULTS

Nine experiments have been done and the corresponding blood and lymph specimens tested as indicated. In no instance was there any indication of a physiologically active substance being present. These negative results, in addition to indicating the absence of a physiologically active substance such as histamine in the shock specimens of blood and lymph, also show that the methods we have employed are free from certain complicating factors. For example, Ponder<sup>3</sup> and others have shown that substances having vascular effects are apt to appear in serums separating from specimens of clotted blood, and Phemister and Handy<sup>4</sup> have shown that blood which has been "traumatized" by shaking or hemolysis and the like also acquires vasodilator and constrictor properties.

When these negative results in the case of surgical shock are contrasted with our positive results in anaphylactic shock, it is at once apparent that there is a distinct difference between the course of events in the two instances. In a typical anaphylactic shock there is an abrupt precipitous fall of blood pressure to shock levels from which the animal may or may not gradually recover. In surgical shock, however, there is a slow, gradual, progressive fall of blood pressure to shock levels from which, as a rule, there is no spontaneous recovery. Depending on the technic used for producing shock, this may take up to an hour or more. Anaphylactic shock, so far as the vascular effects are concerned, can be duplicated by the rapid intravenous injection of a large dose of histamine. It is perhaps not surprising, therefore, that an active agent can be found in the one case and not in the other. Various workers<sup>5</sup>

have noted the inactivation of histamine in intact animals, organ perfusions and the like. We have recently confirmed and extended these observations with respect to the dog and have shown (by the testing methods previously mentioned) that intravenously injected histamine can be detected for only a limited period of time in the blood and lymph.<sup>6</sup> The question therefore arises as to whether surgical shock might not be analogous to the slow, sustained administration of histamine in concentrations and amounts that might ultimately produce a shock level of blood pressure, without attaining detectable levels of concentration in the blood or lymph. The problem thus became one of imitating experimental surgical shock by means of the administration of histamine and determining whether or not histamine activity could be detected in the blood or lymph under these conditions.

We did a great many experiments in which we injected histamine intravenously over periods of time with a modified Woodyatt pump, using varying concentrations of solution. In none were we successful in closely duplicating a corresponding surgical shock experiment. When reasonably strong concentrations were used, the blood pressure would fall rather promptly to a shock level. When weaker concentrations were used, the blood pressure would fall promptly for 10, 20, 30 mm. of mercury or more and then remain at this lowered plateau for rather long periods. There was not the slowly progressive fall characteristic of surgical shock. It is very probable that a suitably adjusted intravenous technic would succeed in duplicating this, but since another method was successful we discontinued our efforts in this direction.

As being more analogous to the theoretical assumption of an absorption of a toxin from a traumatized limb, we then tried subcutaneous and intramuscular injections of histamine into a hind leg. By this technic it is possible to duplicate almost exactly the blood pressure record of a dog during experimental surgical shock. In order to make the duplication as close as possible, a histamine experiment was run simultaneously with a surgical shock experiment. Blood samples could then be taken at corresponding phases of the two types of shock and tested simultaneously. Four such double or twin experiments have been conducted. In each instance the blood samples from the surgical shock animals have been negative throughout, while in each instance of the histamine shock experiments the blood samples taken during the development of the shock have been positive.

These results indicate, it seems to us, that, if surgical shock was the result of a toxemia secondary to the absorption from the traumatized area of a vasodepressor substance such as histamine, it should be possible at some stage of the process to detect the toxin in the blood plasma by the methods employed. Our results, however, have been consistently negative.

#### CONCLUSIONS

1. We failed to find any vasodepressor "toxin" in the blood and lymph of dogs during experimental surgical shock.

2. Experiments indicate that if the vasodepression of surgical shock was due to a toxemia such as that of histamine, the methods employed would have been adequate to detect it.

#### ABSTRACT OF DISCUSSION

DR. CHAUNCEY D. LEAKE, San Francisco: May the disappearance of the vasodepressor substance from the blood or from the plasma on standing be taken in any way as evidence of an enzymatic hydrolysis or destruction of the agent?

DR. CARL A. DRAGSTEDT, Chicago: With regard to that question, the rapid disappearance of histamine from the blood is from the circulating blood. If one draws a specimen and keeps it in the icebox or at room temperature, the histamine activity of that blood will last for hours although it will be measurably deteriorated within a day or so, but it is an entirely different affair from that which occurs while the blood is circulating.

DR. LEAKE: That argues more for an absorption of the material while circulation is occurring.

DR. DRAGSTEDT: Undoubtedly there is a process of inactivation, possibly by histaminase enzymes and possibly by absorption.

#### THE DIAGNOSIS AND CLASSIFICATION OF MENSTRUAL DISORDERS

JOHN C. BURCH, M.D.; G. S. McCLELLAN, M.D.;  
CLAUD D. JOHNSON, M.D.

AND

EUGENE T. ELLISON, M.D.

NASHVILLE, TENN.

The confusion that surrounds the subject of menstrual disorders is largely due to the fact that there has never been any adequate correlation of the symptoms, the endometrium and the underlying glandular disturbance. It is our purpose in this paper to attempt such a correlation. While dysmenorrhea has many points in common with the disorders of interval and flow, it has certain characteristics which set it apart from them, and we reserve it for a separate and later discussion. This paper is limited to the disorders of flow and interval.

In 1929 we began a series of studies on glandular cystic hyperplasia of the endometrium, and, as the results of these studies have been largely responsible for the opinions enumerated in this paper, it seems well to begin with a brief review of them. In our first experiments<sup>1</sup> an analysis was made of the histologic changes produced in the endometrium by the action of estrogen and progestin. The normal human endometrium and the abnormal human hyperplastic endometrium were considered in the light of these studies, and it was concluded that the characteristic picture of glandular cystic hyperplasia of the endometrium was the result of a prolonged, continuous action of estrogen. This was an experimental confirmation of Schröder's concept<sup>2</sup> of the condition. The histologic picture of glandular cystic hyperplasia was next experimentally reproduced in the castrate animal by the prolonged and continuous administration of estrogen (fig. 1). The histologic changes were wholly comparable to changes found in the human being<sup>3</sup> (fig. 2). On account of the importance of this concept of the disease, others have seen fit to repeat and have confirmed these experi-

to the support of these institutions, and those who are responsible for the housing, care, treatment and comfort of persons to be hospitalized.

The determination as to what is the proper space for different types of patients under given circumstances is beyond the range of this article. A few of the facts that have been gathered may be of help in understanding the situation.

the addition of new buildings, giving proper separation and segregation and added equipment facilities. It is generally conceded that the rate at which patients may be discharged is unfavorably affected by a condition of overcrowding.

There is some difference of opinion on the question of rated capacity. The differences, however, are based mainly on estimates of allowances for day spaces, such

Tables 1 and 2 record conditions as of Dec. 31, 1936. Discrepancies between these figures and those found in the list beginning on page 1060 are due to the fact that the list was revised to March 15, 1937.

Superintendents reported that the difference between the crowded capacity and the rated capacity is taken care of by additional cots on porches, in sitting rooms and other day spaces, and in corridors, the temporary cots being removed during the day. Beds are moved together, with no intervening space, in some instances. In some institutions the doctors, nurses and other personnel have labored under great handicaps from overcrowding. It is stated by some that there is no doubt that the percentage of recoveries and the discharge rate among their patients will be definitely increased with

as dining rooms, corridors, occupational therapy units, and other spaces which may be used for sleeping purposes without interfering with the function of the hospital and the comfort of the patient.

The National Committee on Mental Hygiene has made recommendations, and replies to the census indicate that most of the states apparently are trying to take the benefit of the committee's recommendations.

There is general agreement that possibly the most fundamental and, therefore, most suitable basis for calculating rated capacity in state mental hospitals is the

the superintendent, who should take pains to see that copies of the rules and regulations are accessible and well understood. In case of infraction of rules, various forms of discipline have been attempted, such as loss of privileges, public reprimand, withholding of intern

diploma or discharge. Drastic action is seldom necessary whenever a real interest is taken in the welfare of the interns, and regular means are taken to meet with them so that problems may be discussed and solved before serious difficulties arise.

## APPROVED SCHOOLS FOR TECHNICIANS

Preliminary to the formulation and adoption of standards for clinical laboratory schools by the American Medical Association, the staff of the Council on Medical Education and Hospitals inspected and furnished complete reports on 196 schools located in all parts of the country. They included college and university courses, hospital laboratory departments conducting apprenticeship training, and some commercial schools.

With these comprehensive data a true picture of the kind and quality of this type of training was available on which to base standards for acceptable schools.

The "Essentials of an Acceptable School for Clinical Laboratory Technicians," prepared by the Council on Medical Education and Hospitals and concurred in by the Board of Registry of the American Society of Clinical Pathologists, were adopted by the Council on May 10, 1936, and were approved by the House of Delegates of the American Medical Association at the Kansas City session on May 13, 1936.

Since the publication of the first approved list in the Educational Number of THE JOURNAL, Aug. 29, 1936, fifteen schools have been added and one removed.

25. Columbus Hospital and Maynard Hospital, Seattle.

## APPROVED SCHOOLS FOR PHYSICAL THERAPY TECHNICIANS

Following the resolution passed by the House of Delegates at the Cleveland session in 1934 requesting that "some plan for the establishment of standards, ratings and inspections of training schools for physical therapy technicians be effected," the Board of Trustees designated the Council on Medical Education and Hospitals as the proper body to proceed with such a study. The cooperation of the Council on Physical Therapy, the American Congress of Physical Therapy and the American Physiotherapy Association was secured in determining minimum educational requirements for physical therapy technicians.

The "Essentials of an Acceptable School for Physical Therapy Technicians" were adopted by the Council on Medical Education and Hospitals and passed by the House of Delegates at the annual session of the American Medical Association in Kansas City on May 13, 1936. The first list of approved schools was published in the Educational Number of THE JOURNAL under "Survey of Schools for Physical Therapy Technicians," Aug. 29, 1936.

Up to the present time fourteen schools have been approved. Others are in the process of making changes to conform to the standard requirements in order that they may be considered for approval later.

### SCHOOLS FOR PHYSICAL THERAPY TECHNICIANS

- Children's Hospital, Los Angeles.<sup>1</sup>
- Stanford University Hospitals, San Francisco.
- Walter Reed General Hospital, Washington, D. C.<sup>2</sup>
- Northwestern University Medical School, Chicago.<sup>3</sup>
- Bouvé-Boston School of Physical Education, Boston.<sup>4</sup>
- Harvard Medical School, Course 445, Boston.<sup>5</sup>
- Boston University, Sargent College of Physical Education, Cambridge, Mass.<sup>6</sup>
- Battle Creek College, Battle Creek, Mich.<sup>7</sup>

- St. Louis University School of Nursing, St. Louis.<sup>8</sup>
- University of Buffalo, Buffalo.<sup>9</sup>
- Hospital for Ruptured and Crippled, New York City.<sup>10</sup>
- D. T. Watson School of Physiotherapy, Leetsdale, Pa.<sup>11</sup> (affiliated with the University of Pittsburgh).
- College of William and Mary, Richmond, Va.<sup>12</sup>
- University of Wisconsin, Madison, Wis.<sup>13</sup>

### AFFILIATIONS

1. Cedars of Lebanon Hospital, Good Hope Clinic and Los Angeles County Hospital, Los Angeles; Glendale Sanitarium and Hospital, Glendale.
2. Weightmann School for Crippled Children, Washington, D. C.
3. Illinois Central Hospital, Michael Reese Hospital, Montgomery Ward Medical Clinics, Passavant Memorial Hospital and St. Luke's Hospital, Chicago.
4. Boston City Hospital, Children's Hospital, Massachusetts General Hospital and Robert Breck Brigham Hospital, Boston; Cambridge Hospital, Cambridge; New England Peabody Home for Crippled Children and Newton Hospital, Newton.
5. Boston Home for Incurables, Convalescent Home of the Children's Hospital, Children's Hospital, Harvard Infantile Paralysis Commission, Industrial School for Crippled and Deformed Children, Massachusetts General Hospital, Perkins Institute for the Blind and Robert Breck Brigham Hospital, Boston; Cambridge Hospital, Cambridge.
6. Massachusetts General Hospital, Massachusetts Memorial Hospitals and Industrial School for Crippled and Deformed Children, Boston; Cambridge Hospital, Cambridge.
7. Ann J. Kellogg School and Battle Creek Sanitarium, Battle Creek.
8. Firmin Desloge Hospital, St. Louis.
9. Buffalo City Hospital, Buffalo.
10. Cornell Clinic, French Hospital, New York Hospital, New York Polyclinic Medical School and Hospital and New York Post-Graduate Medical School and Hospital, New York City.
11. Allegheny General Hospital, Children's Hospital, Falk Clinic, Industrial Home for Crippled Children and St. Francis Hospital, Pittsburgh.
12. Sheltering Arms Hospital and Stuart Circle Hospital, Richmond.
13. State of Wisconsin General Hospital, Madison.

There is abundant evidence that the Council's program in the regulation of schools for medical technicians is already having the desired effect. The Council is in position to supply reliable information and to guide aspirants in these important fields for the training of medical technicians. Essentials in acceptable schools and lists containing more complete data than those furnished above may be secured on request to the office of the Council.

## HOSPITAL MEDICAL LIBRARY SUGGESTIONS

Prepared by the Council on Medical Education and Hospitals of the American Medical Association

The "Essentials in a Hospital Approved for Training Interns" contains the following provision:

"There must be a working medical library, in charge of a librarian, which should contain a useful selection of late editions of standard text and reference books and current files of not less than ten of the better medical journals. The library should be inside the hospital building and be located where it is readily accessible to the interns and staff members. Collections of choice reference books in pathology and clinical diagnosis and in roentgen-ray work should be found respectively in the pathologic and roentgenologic departments."

Included in the "Essentials in a Hospital Approved for Residencies in Specialties" is the following medical library requirement:

"The hospital shall maintain, or provide ready access to, an adequate medical library containing modern texts and current journals covering the fields in which residencies are offered."

Since the internship must now be considered as the fifth year in medicine and approved residencies in specialties as postgraduate work, hospitals on such educational bases should provide adequate medical libraries.

While it is impossible for all hospitals to be possessed of an ideal library such as may be found in a medical school and in some of the large teaching hospitals, there are few hospitals that cannot maintain a library of a few choice medical periodicals, standard texts and reference books.

The important function of a medical library in a hospital is to provide attending physicians and interns with material for immediate reference and consultation, intensive study of the patients in the hospital, and the preparation of papers, discourses and special reports to be used in staff meetings, medical gatherings and for publication.

### Organization

The medical library should be under the supervision of a committee consisting of several members of the staff. Many library committees are such in name only. Care should be exercised in order to assure the inclusion of such doctors as would take an active interest in developing the library. The funds for regular additions to the library should be placed at the disposal of this committee.

The hospital that has no library may establish one by various means: (a) by an annual appropriation (as little as \$300 annu-

Tables 1 and 2 record conditions as of Dec. 31, 1936. Discrepancies between these figures and those found in the list beginning on page 1060 are due to the fact that the list was revised to March 15, 1937.

ally would be sufficient for establishment and expansion); (b) by annual subscription from staff members; or (c) through gift or endowment in the manner that other equipment and furnishings are given a hospital. A good nucleus, no matter how small, and an assured annual income are the essential requisites of the hospital just beginning its medical library. By the gradual addition of material from year to year a library would be evolved that could be considered an asset to the institution and the community.

The cost of maintaining the library already established is not prohibitive and could be made a legitimate item in the operating budget. When this cannot be done, an excellent plan is for each member of the medical staff to contribute at least a small sum annually toward maintaining and improving the library and this amount could be made a part of the staff dues.

It is desirable that the library should be immediately in charge of a librarian who has had training and experience in library work. In the absence of an experienced librarian, some competent person, frequently the superintendent or record clerk or some other person selected from among the regular administrative personnel, should be placed in charge.

A code of library regulations should be drawn up by the library committee and should be carefully adhered to by the staff members. In general, books or periodicals should not be removed from the library; if this is unavoidable, record should be made of the removal and return.

### Location and Furnishings

The hospital medical library should occupy a prominent location, preferably in the hospital building. The actual location of the room will affect directly the amount of usage. If it is placed in an obscure corner of a floor that is used very little as compared with other floors, it will naturally not be visited often.

The location should be chosen with a view to attractiveness, convenience and comfort to those who will use the library. It is often preferable to have it on the administrative floor or in close proximity to the doctors' room.

The room should be sufficiently large to house the books along with the necessary furnishings, and to permit its comfortable use for reading, discussion and conversation. The very atmosphere of the room will have much to do with the extent to which the library will be used.

It would be worth while for those interested in developing such a library to visit similar libraries and study the elements that seem to make them a success. Any well ordered and well used library, whether medical or not, would furnish good suggestions. The best type of shelf or rack is whatever enables the book or journal to be quickly found, easily removed, and easily replaced. There should be a complete card index. Binding journals into volumes adds to their life and usefulness.

### Reading Matter

In establishing the library, it is well to purchase only one or two comprehensive textbooks on each subject. Only recent books should be chosen, with the exception of such standard works as are recognized as classics in their respective lines, and which do not grow obsolete with age. The literature on therapy and diagnosis, for example, is changing so rapidly as to warrant the use of the most recent books. In the field of the more fully developed sciences, such as anatomy and histology, literature is more stabilized and longer lived. More recent editions of the standard textbooks should be added from time to time, thus keeping the library up to date with regard to new methods of diagnosis and treatment that have been digested and tested. After a good foundation has been formed, the balance of the apportioned funds may be expended in purchasing varied references that are known to be of particular value. The library should not be allowed to become a depository for antiques, and out of date books should be removed or discarded.

The usefulness and efficiency of the hospital medical library depend not only on a good selection of medical books but also on a well chosen group of periodicals. Limited library funds are often more usefully expended for periodicals than for texts and references. When ample funds are provided there is no great difficulty experienced in the matter of choice.

The hospital medical library may supplement its service by the use of state medical school libraries, county society libraries (in some cases), and the package library of the American Medical Association. The package library consists of collections of reprints and other material on various subjects, prepared for lending to members of the Association and to individual subscribers to publications of the American Medical Association. Information on the loan systems of state medical school libraries or society libraries can readily be obtained on inquiry.

Dr. Vincent<sup>1</sup> at the fiftieth anniversary of the Boston Medical Library in 1926, spoke of the library as being part of the social memory:

"A medical group which works with little or no reference to books and journals suffers serious limitations. Without knowledge of what others have discovered, daily experience cannot be resourcefully interpreted. Avoidable mistakes, waste, and duplication of effort are inevitable. Doctors become victims of empiricism and routine; imagination and initiative lack stimulus; enthusiasm and energy decline; minds grow sterile that under the quickening influence of the recorded experience of others might have been fruitful."

Harvey Cushing,<sup>2</sup> in his address at the opening of the new building of the Cleveland Medical Library in 1926, aptly states: "The soul of an institution that has any pretense to learning comes to reside in its library; . . . and no less well may one gauge the quality of a medical school, of a hospital, of a laboratory, of the individual doctor himself, than by the condition of its library."

### SUGGESTED PERIODICALS

A selection of a few leading medical journals is indispensable. Obviously, the average hospital library will contain only a portion of the following list. It is desirable that the library of a general hospital should select its periodicals from those included under "Medicine" and "Surgery" before journals from the special lists are made available. The specialties receive a certain amount of attention in the general medical and surgical publications listed below.

#### ANATOMY

American Journal of Anatomy. Wistar Institute, 36th St. and Woodland Ave., Philadelphia. Bi-M. \$7.50 per volume.

acter of the patients, whether newly admitted, acutely sick, tuberculous, disturbed, noisy, untidy, and the constancy of their presence.

In calculating these allowances it is customary to eliminate toilet, bath and clothes rooms, which are usually a constant quantity, and other spaces, such as narrow corridors, which are not suitable for living purposes.

In populous states like Massachusetts, New York and New Jersey, there is a general tendency to approximate an allowance of 50 square feet floor area per patient in dormitories and day space capacities, around 80 square feet for floor area per patient in single rooms, and around 15 square feet floor area per patient for normal dining room space.

In reporting for the New York State Department of Mental Hygiene, the commissioner said:

As our square foot ratio is fairly generous, we estimate that a general overcrowding of 15 per cent is not apparent.

In the older institutions there was no general standard of certified capacity. The institutions were surveyed from time to time and a reasonable capacity was established for each ward,

and factors of floor space, ventilation, ceiling height, etc., were taken into consideration at that time. With all the new structures, however, we have calculated the certified capacity on the basis of 45 square feet per patient applied to dormitory space only. This does not take into account space in day rooms or in dining rooms. It is on that liberal square foot basis that numbers in excess of the certified capacity easily can be accommodated.

The present satisfactory situation in New York State in respect to lack of overcrowding will not continue unless the state from time to time provides additional accommodations. The normal annual state hospital increase is approximately 2,500. If no provision were made for that increase, the overcrowding would increase at the rate of 5 per cent each year. Fortunately, each year additional funds have been made available and the overcrowding remains about stationary.

### DENTAL SERVICES IN HOSPITALS

Hospitals were asked whether they had dental services, and if so, the number of dentists classified as attending, associate, consulting, and the number of dental interns and number of dentists on salary.

Totals.....	3,142	5,194	1,726	2,025	8,945	211	369	1,176

The tabulation by states published here shows that 3,142 hospitals reported a total of 8,945 dentists. These are divided into attending, 5,194; associate, 1,726 and consulting, 2,025. One thousand one hundred and seventy six of these dentists are on salary. In addition, there are 369 dental interns in 211 hospitals.

## CLINICAL LABORATORY TECHNICIANS

In that part of this Annual Census concerned with technical personnel, all hospitals were asked to report the number of clinical laboratory and other technicians. The response on the question was quite satisfactory. The question gave no definition regarding the qualifications, or standards, as to what should constitute a technician. A total of 3,414 hospitals reported that they employ 6,705 clinical laboratory technicians. Hospitals that said they have no technicians, and those that gave no answer comprised mainly small hospitals and related institutions, such as convalescent and nurs-

All authorities, of course, regard technicians as entirely responsible to the physician-pathologist for the technical procedures carried out.

The Council's investigation and classification of schools for clinical laboratory technicians, as directed by the House of Delegates, resulted in the inspection of 200 schools and the approval of 110 of them, a list of which is found elsewhere in this issue.

## RADIOLOGIC TECHNICIANS

A total of 3,358 hospitals reported that they employ 4,708 radiologic technicians.

ing homes, most of which have their laboratory work done outside.

In California, 183 hospitals employ 418 technicians; in Illinois, 212 hospitals 458 technicians; in Massachusetts, 164 hospitals 375 technicians; in Michigan, 132 hospitals 300 technicians; in New Jersey, 101 hospitals 204 technicians; in New York, 346 hospitals 1,025 technicians; in Ohio, 144 hospitals 317 technicians; in Pennsylvania, 249 hospitals 536 technicians; in Texas, 170 hospitals 288 technicians; in Wisconsin, 111 hospitals 141 technicians.

Only a few states have made statutory provisions for state registration of clinical laboratory technicians. The American Society of Clinical Pathologists has its registry, known as the Board of Registry, in the Metropolitan Building, Denver. Its certificate, based on examination and other requirements, is used to a growing extent by hospitals in the considering of applicants.

Here again the question asked simply how many radiologic technicians are employed. It is generally understood that all procedures undertaken by technicians are under the supervision of the staff. A registry known as the American Registry of X-Ray Technicians is under the auspices of the Radiological Society of North America. The office of the registry is at Oak Terrace, Minn.

There are schools for the training of radiologic technicians, but no program of requirements and approval has been put into operation.

## DIETITIANS

The number of hospitals reporting that they employ dietitians was 2,878, and these hospitals have a total of 4,331 employees serving in that capacity. The term "dietitian" was used without definition, leaving the interpretation to the person answering the questionnaire.

There appears to be no statutory requirement in any state regulating the practice of dietetics. Each hospital and each department of the government sets its own standards for employment. Many hospitals, some state governments and some departments of the federal government specify membership in the American Dietetic Association. The association, with offices at 185 North Wabash Avenue, Chicago, has approximately 3,500 members, 70 per cent of whom are serving in hospitals. It upholds the standards of admission to, and curricu-

tional procedures in hospitals, as directed and supervised by the medical staff. Standards have been put into effective operation by the Council on Medical Education and Hospitals with the cooperation of the American Occupational Therapy Association. Hospitals play an important part in the training of students in occupational therapy. It is not uncommon to find ten or more graduate occupational therapists employed in a single state mental institution, and one of these employs twenty.

Technical Personnel Employed in Hospitals

\* Data concerning the Council's lists of approved schools for clinical laboratory technicians, occupational therapy technicians and physical therapy technicians are presented in a later section of this article.

lum in, its approved training courses. These courses number about fifty, and they may be taken in a single hospital, but more commonly there is an affiliation to supply a balanced training, including infant feeding.

OCCUPATIONAL THERAPY TECHNICIANS

In response to the question asking how many occupational therapists are employed, 792 hospitals gave a total of 1,809 therapists. The greatest number of these are employed in mental hospitals, which claim a total of 1,062; tuberculosis hospitals employ 153 therapists; orthopedic hospitals, 36; general hospitals, 456, and all other institutions, 102.

In the absence of statutory requirements, a national registry is maintained by the American Occupational Therapy Association, the office of which is at 175 Fifth Avenue, New York City. That association fosters high standards for the application of therapeutic occupa-

PHYSICAL THERAPY TECHNICIANS

Thirteen hundred and two hospitals reported 2,382 physical therapists. The greatest number of physical therapists, 1,648, appears to be serving in general hospitals. Other types of hospitals reported as follows: mental, 350; orthopedic, 167; tuberculosis, 62; children's, 41, and all other institutions, 114.

Under the heading of physical therapy there is a variety of technical help, some of whom are skilled in general procedures while others specialize in massage, hydrotherapy, electrical or other forms of therapeutics. Their registry, which is likewise on a voluntary basis, is known as the American Registry of Physical Therapy Technicians, located at 30 North Michigan Avenue, Chicago. The registry is comparatively new. As of March 1, 1937, it had received 183 applications and had issued certificates to fifty-nine persons.

A program of standardization and classification has been successfully carried out by the cooperative effort of the Council on Physical Therapy and the Council on Medical Education and Hospitals. After inspection by the latter council a list of acceptable schools was recommended and was adopted by the House of Delegates at the Kansas City session. The list appears in a later part of this article.

#### PHARMACISTS

A total of 1,419 hospitals reported that they employ 1,901 pharmacists. Most, or all, of the states of the Union have laws regulating the practice of pharmacy, the handling of drugs in hospitals, as well as elsewhere, and provisions for registry under the state government.

The "Essentials of a Registered Hospital" require that "the handling of drugs should be adequately supervised and should comply with state laws."

#### DENTAL HYGIENISTS

Three hundred and ninety-four hospitals require 484 dental hygienists. The greatest number of hospitals employing this class of help was New York, in which

fifteen hospitals and eighteen hygienists, and Texas, thirteen hospitals and fourteen hygienists. Several well regulated schools form a source of supply.

#### SCHOOLS OF NURSING

The accompanying table on schools of nursing and students enrolled gives data that are of special interest inasmuch as they compare the census for 1936 with those of 1926 and 1932.

*Schools of Nursing*

	1926	1936
In general hospitals.....	1,925	1,364
In mental hospitals.....	91	51
In tuberculosis hospitals.....	25	16
All other hospitals.....	52	47
Not reporting.....	62	
Totals.....	2,155	1,478

Average number of students per school.....				36	45	48

eighty-nine hospitals employ 108 dental hygienists. Next in order are Pennsylvania, with fifty-four hospitals and seventy hygienists; Massachusetts, thirty-two hospitals and thirty-seven hygienists; California, twenty-three hospitals and thirty-three hygienists; Illinois, seventeen hospitals and nineteen hygienists; Michigan,

The table gives for each state the number of schools of nursing and the number of students enrolled in each of the three years. All schools of nursing that reported—both approved by state boards of nurse examiners and unapproved, are included.

The total number of schools of nursing reported in hospitals in 1926 was 2,155; those reported in 1936, 1,478, a shrinkage of 677 in number of schools. At the same time, however, the reduction in the number of students enrolled was less marked, the figures being 76,527 in 1926 and 72,174 in 1936. The percentage of decrease in schools, using the number existing in 1926 as a basis, is 31 per cent. The decrease in students, using the number enrolled in 1926 as a basis, is 5.7 per cent.

The average number of students per school increased from 36 in 1926 to 48 in 1936. Prior to 1930 the Hospital Information Blank (Annual Census questionnaire), used the term "nurse training school." Since 1930, however, the term "school of nursing" has been used. This was fostered by the Committee on Grading, which was actively engaged in its survey during the late twenties and the early thirties, and which gave the country volumes of data and comments concerning its findings in the field of nursing education. The impression is widespread that the closing of many schools was caused by information supplied by that committee that there were too many nurses. The raising of standards

for the training of nurses also is given as a cause for the reduction in the number of schools.

Among the states in which there has been a marked decrease in the number of schools of nursing, and likewise fewer students enrolled, are Alabama, Arkansas, Georgia, Iowa, Kentucky, Minnesota, Nebraska, Oklahoma and Wyoming. On the other hand, a decided decrease in the number of schools has been accompanied with a marked upturn in the number of students enrolled; for example, Florida, Indiana, Kansas, Mary-

land, Massachusetts, New Jersey, Ohio, Tennessee and Vermont. Nebraska reports exactly one half as many schools as formerly, a drop of 28 to 14. Virginia has reduced its number from 48 to 26, the number of students enrolled dropped from 1,295 to 1,174.

Other striking contrasts are readily observed in the table.

The types of hospitals having schools of nursing in 1926 and 1936 are shown in a table on page 1047.

Of the 1,478 schools of nursing reported in the 1936 census, 1,420 are accredited by the board of nurse examiners of the state in which the school is located.

HOSPITALS REFUSED REGISTRATION

There are 581 institutions which, because of alleged unethical or questionable practices, admission to their staffs of members who are seriously unqualified, either morally or professionally, flagrant methods of advertising, or for other valid reasons, are deemed unworthy of being included in any published list of reputable hospitals.

Only a little over 1 per cent of the total capacity of all hospitals is included in the 581 institutions that are refused registration. From the standpoint of hospitalization, therefore, they are as a rule not needed. Not only are they left out of the Register and American Medical Directory but their names are consistently

omitted from all the publications of the Association and they are refused admission to the advertising columns.

This helps to distinguish between the good and the bad in hospitals. As a result, it is considered a disgrace among hospitals and physicians to be refused registration, and institutions that are rejected are frequently aroused and correct the objectionable practices in order that they may be recognized. Public and professional opinion forces many such institutions to sell their buildings to more reputable owners or to close up.

The Register is used as a basic list of hospitals. Industrial and governmental agencies use it in selecting hospitalization for their dependents and beneficiaries. Physicians almost universally observe the Register in referring their patients.

## INTERNSHIPS AND RESIDENCIES

Statistical data presented in the accompanying tables represent a close estimate of the present status of internship and residency approvals. It is of considerable interest to note that the selected group of hospitals included in the tables have a bed capacity of 369,478. Admissions amounted to 4,596,453, or over half the total annual admissions in the entire group of 6,189 registered hospitals.

The importance of the totals expressed in the two tables becomes clear when it is demonstrated that approved hospitals require the services of two complete graduating classes from the medical schools, an indication that present day graduates find it desirable to extend the period of training at least two years beyond the date of graduation. The first six columns in the table offer figures on intern supply and demand. According to these statistics, there were 6,923 appointments in approved internship hospitals Jan. 1, 1937. Interns employed in these institutions served a total of 107,999 months or an average length of service of 15.6 months. The total number of appointments available annually therefore is reduced to 5,510. This compares

who are accepted for appointment in approved hospitals. It would appear, however, that the 711 approved internship hospitals provide a sufficient number of annual appointments to place the group of well qualified candidates.

The increasing number of residencies represents a counterbalancing tendency to the increasing length of

*Internship and Residency Statistics—March 15, 1937*

Hospitals approved for interns and residents.....	939
Bed capacity.....	369,478
Admissions during 1936.....	4,596,453
Number of approved internship hospitals.....	711
Number of interns serving in approved hospitals.....	6,873
Number of unapproved hospitals employing interns.....	262
Number of interns in unapproved hospitals.....	554
Total interns.....	7,427
Number of hospitals approved for residencies.....	430
Number of residents in approved positions.....	3,067
Number of residents in unapproved positions.....	1,321
Total residents.....	4,384
Total interns and residents.....	11,811

the internship period, since it permits further hospital training without directly reducing the number of first year appointments. There is a definite preference on the part of hospitals training both interns and residents to promote their own house officers to higher appointments. In consequence, considerable difficulty is experienced by a great many qualified applicants who attempt to break into the ordinary hospital residency system.

The calculations on salaries in the same tabulation include all regular allowances and bonuses as reported for Jan. 1, 1937. The list of average salaries granted refers to the paid group only and does not represent a figure for the entire intern population. However, on the basis of these statistics, it would appear that the total annual amount paid out in salaries to all interns is \$1,316,153.28, or \$17.44 per intern monthly. No accurate figures are available on the cost of maintenance, which in practically all instances includes at least lodging, board and laundry.

WHAT SHOULD THE HOSPITAL EXPECT  
OF AN INTERN?

Increasing attention in recent years has been paid to the internship. Reviews of present requirements, current status and advancing standards have regularly appeared in the Hospital and Educational numbers of THE JOURNAL. The demands made on hospitals are, as a result, well known both to the institutions themselves and to the candidates who elect to serve in them. The rate of acceptance of suggested changes has been variable but steady, depending largely on economic feasibility. For the most part, approved hospitals understand that any contribution they make in the form of an educational service yields a return in self improvement beyond any immediate result obtained by the individual apprentice. The campaign of the Council on Medical Education and Hospitals to elevate the character of intern training has provided the stimulus for adoption of many improved methods of patient care. At present a dwindling minority of hospitals exists in which there is little appreciation of educational values and which still in a number of ways exploit their house officers.

In the face of this widespread concern for the welfare of interns, a hospital may ask whether or not house officers take full advantage of opportunities and whether the expense and the effort are fully justified.

with 5,247 fourth year medical students during the period 1935 to 1936, or an excess of appointments over applicants of 263. The fact that 554 interns are employed in unapproved hospitals is of some importance in this general balance although many so serving are graduates of foreign schools or low grade schools in this country. An additional factor not considered in these tables concerns graduates of Canadian schools

Since the internship system persists and improves, it would appear that most interns respond sufficiently well to warrant continued maintenance of the required facilities. There are enough of the other variety, however, to constitute a constant problem.

Although the average age of medical graduates approximates 26 years, experience has taught hospital authorities that interns cannot uniformly be treated as mature professional men and women. It is difficult for an attending physician to understand how a mature person can ignore obvious means for improving his clinical knowledge by failing to appear at rounds, outpatient clinics, necropsies and conferences, ignoring the

Granted that a hospital can supply an educational service in keeping with standard regulations, what ought it to expect of its interns and what adjustments can readily be made to reduce the main sources of friction? Obviously it should be expected that interns observe provisions stipulated in the internship contract and that they faithfully observe hospital rules and regulations.

#### INTERNSHIP CONTRACTS

Hospitals have difficulty with two main types of men who break internship contracts: (1) those who accept several appointments at the same time and (2) those who leave the hospital before the stipulated term of service is completed.

There will be no real solution of the first type until there is general adoption of uniform methods and time of intern appointment, possibly as suggested in the Hospital Number, March 30, 1935. Until such time, several helpful methods can be adopted; for example, the contract form should be kept entirely separate from the application blank and in every instance should clearly stipulate the beginning and terminating dates of the appointment. Hospitals should carefully avoid any possible misrepresentation of the character of the teaching service. A number of the better hospitals supply a prospectus to applicants outlining the principal attributes of the service, covering available clinical material, schedules of assignment, and important teaching exercises. An abstract of the last inspection report on the internship program prepared by the Council's staff would serve satisfactorily. With such information at hand, little excuse could be advanced by an intern for departure from the hospital in advance of the regular termination date on the basis of provision of an inadequate educational service alone. Finally, if each approved hospital would assure itself, by means of a suitable question on its application form, that the candidate under consideration is not under contract to any other hospital, the problem would be largely solved. The Council has means of determining the names of interns who fail to serve for the full appointed time and makes its own inquiries. Records of all broken internship contracts are maintained in the biographic files of the Association, details of which are available to those who may inquire.

The desire to terminate a service may rise from sound reasons. Most often this step is a misguided one and represents disregard of any obligation to the hospital or to the other interns. In any case, the request to leave should be made in writing, stating reasons, at least two weeks in advance to allow for proper investigation of the validity of the petition. The hospital may expect that a satisfactory substitute be provided in all cases in which the departure of one means disruption of the services of the remaining interns.

#### RULES AND REGULATIONS FOR INTERNS

A rule of conduct for interns could be most simply expressed by saying that the hospital and its staff expect that house officers behave like professional gentlemen, to which, by way of elaboration, might be added that interns be acquainted with their duties, perform them cheerfully and promptly, and in their performance respect hospital property and economize in the use of supplies. Most hospitals have found it necessary to expand these simple regulations considerably.

Enforcement of the house staff regulations should be a combined function of the staff intern committee and

\* Includes all laboratories reporting directors other than M.D. and all hospitals reporting a laboratory without specifying type of director.

medical library, spending as much time as the rules permit outside the hospital and exhibiting such a general lack of concern about his patients as to cause wonder why he finds it necessary to mark time for an entire year or longer unprofitably. The answer is twofold: such interns have no real appreciation of demands made on practitioners and they lack the ability to adjust themselves to personal responsibility. Both of these deficiencies are attributable in part to the failure in some of the medical schools to develop the student's sense of responsibility through an adequate clerkship and in part to the fact that a certain proportion of medical students are temperamentally unsuited to practice and consequently never acquire that personal interest in patients which is characteristic of the real physician.

ments. Among them are Parkes,<sup>4</sup> Tietze,<sup>5</sup> Kaufmann<sup>6</sup> and Zuckerman and Morse.<sup>7</sup>

Since glandular cystic hyperplasia of the endometrium is the result of the prolonged continuous secretion of estrogen, it cannot occur in patients whose ovaries contain active corpora lutea. In other words, in these cases the corpus luteum has failed, and estrogen alone continues to exert its influence on the endometrium. Such an ovarian state is clearly the result of a partial failure of ovarian function, and it seemed wise to try to produce such a condition of partial ovarian failure in our animals. We therefore partially castrated a series of animals and observed the sexual cycle<sup>8</sup> (fig. 3). In one group there was but little or no disturbance in the duration of the cycle and the extent of the estrous periods. In another group there was an irregularity of the interval and a prolongation of the estrous periods. In the remainder there was a greatly prolonged interval or an entire absence of the cycle. In the first group of animals the endometrium showed slight deviations from the normal; in the second

Further it seemed eminently desirable to compare the endometrium of animals with deficient hypophyseal function with the endometrium of animals with deficient ovarian function. Accordingly a group of animals were partially hypophysectomized and the cycles and

Fig. 1.—Endometrium of guinea-pig showing glandular cystic hyperplasia produced by long continued injection of estrogen.

they were frankly hyperplastic (fig. 4), and in the third they were partially atrophic and tended toward the castrate type. The endometrium of the animals in the second group, showing glandular cystic hyperplasia, was just as comparable to the human condition as that seen in the previous experiments, in which estrogen was given over a considerable period of time.<sup>3</sup>

Having shown that the condition of glandular cystic hyperplasia of the endometrium can be produced by surgically reducing the functional capacity of the ovary, it seemed wise to consider the effects of reducing ovarian function by other means. It was only natural that we should turn to the hypophysis on account of its well known rôle in directing ovarian function.

Fig. 2.—Human endometrium showing glandular cystic hyperplasia.

endometrium studied. The cycles fell into the same groups (fig. 5), and the endometrium was identical with that in the hypo-ovarian series (fig. 6).

Fig. 3.—Vaginal smears of guinea-pigs for 110 days following extreme partial castration.

We have interpreted these experiments as indicating that ovarian function can be reduced by lesions affecting the ovary or by lesions affecting the hypophysis or other endocrine glands. We have designated the two types as primary ovarian failure and secondary ovarian failure. Both primary ovarian failure and secondary ovarian failure produce the same changes in the endo-

metrium. These changes indicate the degree of ovarian failure and have been designated as first degree, second degree and third degree. It is of course obvious that the complete detailed presentation of all the experiments is impossible here.

Fig. 4.—Endometrium of guinea-pig showing glandular cystic hyperplasia produced by partial castration.

In our clinical studies on the human endometrium our biopsy technic has given us an unusual opportunity to study the endometrium of the same patient over a

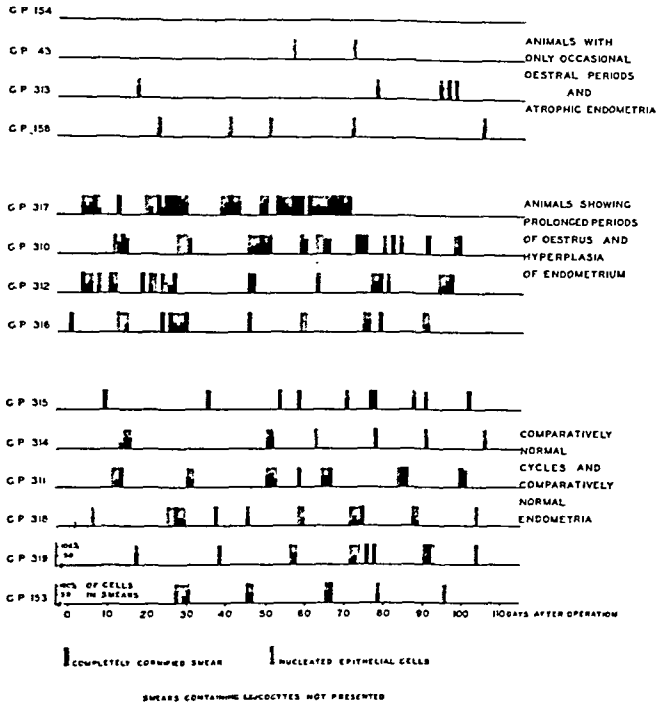

Fig. 5.—Vaginal smears of guinea-pig for 110 days following partial hypophysectomy.

long period of time.<sup>9</sup> Numerous instances of the progression of one type of endometrium into another have been noted. The primary trend of the progression is

toward an endometrium indicating lower degrees of ovarian function, although the progression is frequently interrupted by remissions and reversions to a more normal endometrium. Hyperplasia frequently reverts toward the normal. In a general way we have classified those syndromes described as luteal menorrhagia, irregular shredding of the endometrium, and corpus luteum persistans as first degree ovarian failure, glandular cystic hyperplasia and aluteal menorrhagia as second degree ovarian failure, and those syndromes associated with the atrophic aluteal endometrium as third degree ovarian failure.

In correlating the symptoms with the endometrium it has been noted that there is no single set of symptoms specifically characteristic of any grade of ovarian failure. There is, however, a tendency for the minor disturbances of flow and interval to fall into the first group, for the severe bleeding to occur in the second, and for the amenorrheas to fall into the third.

With the preceding clinical and experimental background it seemed wise to study a group of patients

Fig. 6.—Endometrium of guinea-pig showing glandular cystic hyperplasia produced by partial hypophysectomy.

with menstrual disorders in regard to the degree and type of ovarian failure. The degree of ovarian failure was determined from the endometrium taken on the first day of bleeding. The type of ovarian failure, whether primary or secondary, was determined from a study of the endocrine status of the individual carried out along the lines advocated by Rowe<sup>10</sup> and Lawrence and summarized by Rowe in Meaker's book, with the addition of Goldzieher's test for the specific dynamic action.<sup>11</sup> This matter was fully discussed before this section in two papers at the last session.<sup>12</sup> In addition to a careful general history, physical examination and the usual laboratory studies, the determination of the basal metabolic rate, the specific dynamic action of protein according to Goldzieher's method and of the sugar

tolerance according to Rowe's galactose method<sup>13</sup> were done on all patients. In arriving at a diagnosis the history, physical examination, routine laboratory and special tests were all considered in the light of the generally accepted views concerning the changes produced in endocrine diseases. The more important of these are shown in table 1. In all, thirty-one cases have been studied. The usually accepted deviations of the special tests in endocrine disease are shown in table 1. The cases are presented with the results of examination classified according to the diagnosis in tables 2, 3, 4 and 5. The averages of the basal metabolic rate, the specific

not always clear. Admitting these weaknesses and the fact that as knowledge advances our conception of endocrine disease will materially change, we nevertheless believe that the clinical data, taken as a whole, strongly supports our experimental observations.

dynamic action of protein and the galactose tolerance test for the groups and for the series are given in table 6.

COMMENT

The experimental data clearly show that primary and secondary ovarian failure are capable of producing the same endometrial lesions. The clinical correlation of symptoms and endometrium indicates that there is no single endometrial lesion always associated with a specific menstrual history, although there is a general tendency for certain symptoms to predominate in certain groups. We are not prepared to defend the accuracy or specificity of the tests in all instances. In some instances, undoubtedly, a case has been incorrectly classified, as the lines of division between the types are

Average	10	32	-6.7	2.5	21	

Our clinical and experimental observations indicate the fallacies of present treatment. Serious discrepancies arise over the relative merits of the various treatments for the disorders of flow and interval. Some put their faith in thyroid, some in extracts of pregnancy urine and others in pituitary extracts or substance. All these

13. Rowe, A. W.: Sugar Tolerance as an Aid to Diagnosis, J. A. M. A. 89: 1403 (Oct. 22) 1927.

are good in a certain percentage of cases but fail in the majority of instances. Since evolving this conception of menstrual disorders we have treated, to the best of our knowledge, the primary focus of the disease. It is still too early to evaluate this treatment clearly but our clinical impression is one of a definitely improved therapy. Surgery, of course, has been necessary in some, and the results as usual are brilliant. It should be borne in mind that, no matter how brilliant the surgical result, it is at best a symptomatic cure. The glandular disturbance is not removed, and most active surgeons will find several instances among their patients in which the symptom has been surgically relieved but the endocrinopathy remains to invalid the patient.

CONCLUSION

We conclude that the disorders of menstrual interval and flow are the result of an ovarian underfunction. The severity of this underfunction is indicated by the state of the endometrium. The ovarian condition may be the result of a primary lesion in the ovary or may arise as a secondary manifestation to a lesion in other endocrine glands. Crude clinical methods are at hand for the determination of the type of endocrinopathy present. Intelligent treatment must consider these facts.

ABSTRACT OF DISCUSSION

DR. J. P. PRATT, Detroit: The title as stated is not entirely justified by the material offered, because menstrual disorders have not been classified in the paper. The authors have presented, however, an enumeration and correlation of some of the causes of menstrual disorders. The method of studying changes in the endometrium by repeated biopsies is a creditable contribution, but interpretation of the entire endometrium from a small fragment of tissue incurs certain difficulties. Bartelmez, who has studied the endometrium of uteri during menstruation,

concludes that the only characteristic of normal menstrual endometrium is bleeding. He finds in the same specimen areas of desquamation, regeneration, hemorrhage and progestational hypertrophy. Biopsies taken on the first day of bleeding might not indicate, therefore, the true state or even the average of the whole endometrium. On the other hand, if a large number of specimens are available for comparison, they have at least a relative value. The postulate that, "since glandular cystic hyperplasia of the endometrium is the result of the prolonged secretion of estrogen, it cannot occur in patients whose ovaries contain active corpora lutea," may be questioned. It is well known that estrogenic substances are normally secreted by the ovary throughout the cycle. The source of this secretion is not only the granulosa cell but also the luteal cell. Furthermore, hyperplasia of the endometrium does occur in the presence of corpora lutea as well as in their absence. The microscopic appearance of such corpora lutea indicates a normal activity. May it be a question then of definition of hyperplasia of the endometrium? Only underfunction of the ovary has been mentioned as a cause of menstrual disorder. Is hyperfunction intentionally denied or implied? If so, how should one explain the increased flow associated with inflammations involving the ovaries? The quantitative changes in function have been well emphasized, which correctly implies that qualitative changes in ovarian secretion do not occur. It is true that different hormones have been isolated from the ovary, theelin and its derivatives and progesterin. The evidence so far presented indicates variation in quantity of these hormones and not their quality. While considering the influence of other glands on the uterus through the ovary, might it not be well also to consider a possible change in receptivity of the uterus? No doubt the ability of the endometrium to respond is conditioned by a number of agents. The study of menstrual disorders is complicated. The authors wisely claim no finality.

DR. E. C. HAMBLEN, Durham, N. C.: During the past two years my associates and I have studied 358 consecutive patients with functional bleeding. Clinical and laboratory data in these cases have been correlated. The responses to various forms of therapy have been considered. Specimens of endometrium from these cases available through biopsy, curettage and hysterectomy have been reviewed. In instances in which laparotomies have been necessary, the gross appearance and measurements of ovaries have been recorded and, where ovarian material has been available for microscopic studies, the entire material has been reviewed. Of these 358 patients, 172 were bleeding actively at the time the endometrial specimens were obtained. Of the latter, 146 were bleeding from an interval type of endometrium which showed no evidence of tissue shedding. In this group of cases, four general patterns of endometrium were observed: an atrophic or senile pattern, attributed to an anestrogonic or hypo-estrogonic phase, was observed in 38 cases; an early or midinterval pattern, not different histologically from the usual estrogenic phase, occurred in six cases; a pattern that showed moderate irregularity in gland size but without evidence of thickening or hypertrophy, attributed to an arrested estrogen phase, was found in thirty-four cases; actual endometrial hyperplasia of the classic type, attributed to a phase of prolonged estrogenic action, was observed in sixty-eight cases. Of the twenty-six cases in which bleeding occurred from endometrium in which there were progestational glands, nine showed no evidence of tissue shedding, eight showed irregular and incomplete shedding and nine showed tissue loss characteristic of the normal menstruating endometrium. Patchy distribution of the progestational glands characterized those instances in which no tissue loss was observed. In five cases there had occurred apparently a progestational phase following a phase of estrogen arrest, while in four cases this progestational reaction had followed a phase of prolonged estrogenic action. It is evident that functional bleeding occurs in the vast majority of instances from an estrogen type of endometrium. Only about 45 per cent of such cases showed the classic pattern of endometrial hyperplasia. We object to the term endometrial hyperplasia, especially when used to cover the various patterns of estrogen or interval endometrium associated with functional bleeding. Dr. Burch and his associates have essayed a difficult task in attempting to diagnose and classify menstrual disturbances, especially those cases in which the ovarian-endometrial disturbance is secondary to dysfunction in other endocrine glands, such as the pituitary and thyroid.

JOHN C. BURCH, Nashville, Tenn.: The term endometrial lasia is, perhaps, a bad one. We have recognized this discussed it at length in previous papers. The general use of the term should help in clearing up the terminology. True ar cystic hyperplasia of the endometrium does not and occur in the presence of an active corpus luteum. The e of the corpus luteum in sufficient concentration and over sufficient time produces certain characteristic in the estrogen sensitized endometrium. In the early of its action the changes in the endometrium may be sed, but these changes should be definitely present by time of menstruation. If they are overlooked, it is because the action of the corpus is abnormally weak or absent altogether. If a mistake in diagnosis is made at this time, it is of only theoretical importance, as it makes little practical difference whether the case is classified as a severe first degree failure or a mild second degree failure. The biopsy instrument has been of considerable of help to us. It is a reliable and safe procedure for obtaining endometrial tissue in the office or clinic. Anesthesia is not necessary. The amount of tissue obtained has been adequate for our purposes. If more is desired, the instrument can be inserted a number of times. The mechanism of bleeding in pelvic inflammation is not settled at present. Some cases of bleeding are probably the direct result of damage to the ovary, while others are not. Fluhmann discussed the question in a paper before this section five years ago.

## MANAGEMENT OF FACIAL INJURIES CAUSED BY MOTOR ACCIDENTS

CLAIRE L. STRAITH, M.D.

DETROIT

In its relatively short career, the motor car has already brought about more casualties in the United States than all the wars in which this country has been engaged. In 1935 alone, motor car accidents caused approximately 36,000 deaths and a far greater number of severe injuries. So serious has the situation become that traffic and safety engineers, public officials and educators have set about intensively to seek a solution of this problem. Safety campaigns have stressed the harrowing picture of "Sudden Death."<sup>1</sup> More tragic than sudden death, however, is the suffering borne by the injured who escape it. And more pitiable even than the immediate period of pain and disability is the suffering, through long bitter years of mental agony, of those left with lasting, conspicuous facial disfigurements.<sup>1</sup> The psychologic handicap imposed by unprepossessing or even relatively minor disfigurements has helped to blight many promising business and social careers and has helped to swell the ranks of the unemployed and unemployable.<sup>2</sup>

Hence the need of again calling attention to certain essentials in the management of acute facial injuries and their late sequelae. The hasty "emergency care" usually given these victims often jeopardizes the possibility of a good end result. The necessity of careful, meticulous care according to well established principles derived from experience with such injuries cannot be too strongly emphasized.

Facial injuries resulting from motor accidents may be classified according to two general types: (1) inju-

ries to the driver ("steering post injuries"<sup>3</sup>); (2) "guest-passenger injuries." These two types, because of the different factors which produce them, are usually quite distinctive.

"Driver injuries," because of the relative protection afforded the driver by the steering wheel to which he may cling for support, are the least frequent variety. It is remarkable how often, even after a violent smash-up, the driver emerges free from injury. If, on the other hand, the driver relaxes his hold on the wheel, falls asleep or is subjected to an unusually sharp impact, his head may be projected forward so that the chin strikes the center of the wheel.

This results in a typical "steering post injury," namely, laceration and contusion of the chin associated with fractures of the mandible (symphysis, necks of the condyles, and so on). When the force of the impact is even greater, the head may be projected forward to the point where the face is thrown down on the steering wheel. In such instances the upper jaw (maxilla, malar bones) receives the brunt of the blow (fig. 1).

"Guest-passenger injuries," i. e., injuries of persons riding in the front seat beside the driver, are more frequent. In my experience they constitute about 75 per cent of severe, crushing, facial injuries sustained in motor accidents. The majority of these victims are young women. Lacking the support of a structure comparable to the steering wheel, guest-passengers are thrown forward more violently at the impact. The injury is sustained when the head strikes the instrument panel with resultant crushing of the midportion of the face. These injuries—chiefly fractures and depressions—involve the maxilla and the nasal and malar bones as well as the orbit and eyeball. Projecting objects on the instrument panel (handles, knobs and cranks) add to the hazard.

Fig. 2.—Guest-passenger injury. Fractured nose, malars, maxilla and mandible.

Read before the European Congress of Plastic Surgeons in Brussels, Belgium, Oct. 4, 1936.

Owing to lack of space, a number of illustrations have had to be omitted from this article as published in THE JOURNAL. The complete article will appear in the reprints, a copy of which may be obtained on application to the author.

ANN ARBOR

Elimination of such objects from the passenger's side of the instrument panel should be attempted by motor car engineers. The use of "crash padding" might do much to minimize the seriousness and extent of these injuries (fig. 2).

#### PRELIMINARY EXAMINATION AND TREATMENT

To obtain successful and satisfactory end results in the surgical treatment of these injuries, a systematic

Fig. 3.—Author's apparatus for treating fractured facial bones. Head band has anterior and lateral binding posts and knobs for suspension of maxillary fractures and other attachments. There is an adjustable nasal assembly for elevation of the nasal bridge and compression of the sides of the nose and a maxillary splint adjustable to different size jaws with fixed side arms for upward traction if needed. The head band should be embedded in a plaster cast for proper fixation.

examination of the patient is of primary importance. The following routine is suggested:

1. *Careful inspection and cleansing of all lacerations, with removal of gross foreign bodies.* This is a very necessary and important first step, which must not be neglected. Hurried closure of wounds with skin clips and heavy suture materials (heavy silk or catgut) is to be condemned. Surgical repair should not be attempted until it can be done properly under conditions that will leave a minimal scar.

Fig. 4.—Double subcuticular stitch leaves the finest scar. Deeper tension stitch of dermal or other strong material is used and the exact approximation of skin edges is accomplished by a fine horsehair stitch.

2. *Careful palpation of all facial bones.* Using both index fingers, the operator should carefully palpate the forehead, orbital rims and zygoma. Separation of the malar attachments, depressions and eversion of the zygoma and depressed malar fragments at the infra-orbital foramen may thus be detected. The latter condition can also be recognized by intra-oral palpation with the index fingers, which detects prominent bone

edges. Anesthesia of the lateral surface of the nose and upper lip on the affected side is a frequent finding in these fractures.

3. *Palpation of the nose and intranasal inspection.*

4. *Inspection and palpation of the oral cavity.* This step is of extreme importance, since it will often reveal maxillary lesions otherwise overlooked, lateral or downward displacement of the maxilla caused by transverse fracture, and midline or unilateral maxillary compression fractures. Mandibular fractures usually are easily recognized. When chin lacerations are present they should always be suspected and a careful search should be made to determine the presence of fractures of the necks of the condyles. Backward displacement of the mandible in fractures of the condyles may give rise to serious respiratory difficulties that require immediate attention (fig. 1).

#### WOUND CLOSURE

Every effort must be made at the onset to conserve tissue. Hence severed portions of skin (after denuding the subcutaneous fat) should be replaced immediately and sutured in place in the manner of a Wolfe graft.

Fig. 5.—Plaster head cap makes excellent firm attachment for nasal appliance. Nasal bones were held up and lateral pressure applied by author's appliance. Maxillary splint was held up by elastic traction to coat hanger wire attachments embedded in plaster cap. Light elastic should be used or an impaction of the maxillary fracture with overcorrection may be produced. These side arm splints have now largely been discarded.

This is followed by the application of a pressure dressing. The abundant circulation of the face will often save an apparently useless skin flap. The same applies to ears and nasal tips that have been partially or almost completely severed.

After the wound has been carefully cleansed, the jagged skin edges are trimmed to straight lines. Buried dermal sutures are then placed to relieve tension. I prefer a double subcuticular stitch, since it leaves the least conspicuous scar. Deep skin layers are approximated by a subcuticular stitch of dermal or other fine though strong suture material. The surface is approximated accurately with a subcuticular horse hair suture threaded on a small eye-needle, which is passed just beneath the surface epithelium. In long wounds the stitches should be brought to the surface at intervals of one inch so that they may subsequently be cut and removed in sections. The horsehair suture is removed in forty-eight hours, the other sutures in from seven to ten days (fig. 4).

Interrupted sutures of horsehair may also be used for skin approximation. Stitch marks will be avoided if only the first double twist is used in tying the surgical knot.

#### FRACTURES

**Nasal Fractures.**—Simple nasal deviations can often be corrected by thumb pressure under local anesthesia. Nasal bones torn loose from the frontal bone must be brought back to their normal position and wired to the frontal bone through drill holes placed in each bone. In crushing nasal injuries I prefer to raise the nasal bones under local anesthesia and apply a plaster head cast and a special splint which holds the nasal bones in place, shapes them by lateral pressure and, at the same time, permits nasal drainage (figs. 3, 5 and 6).

**Malar Bone Fractures.**—Fractures of the malar bone, if left untreated, leave very conspicuous deformities. Hence every effort should be made to restore and main-

Fig. 6.—Profile view six months after patient was treated for crushed nose and maxilla. The teeth are in excellent occlusion and the nose is well formed.

tain proper elevation. This can be accomplished by several methods: 1. Grasping and elevating the bone by means of a large towel clip inserted through an incision in the lower eyelid and cheek (Gill<sup>4</sup>). 2. Opening the canine fossa and elevating the malar bone through the antrum; if necessary to maintain elevation, the antrum may be packed. 3. Elevating the malar bone by means of an antrum trocar inserted into the antrum through the nose (Shea<sup>5</sup>). 4 (author's method). Passing an antrum trocar or a heavy curved instrument through the mucous membrane behind the last upper molar up and beneath the malar bone behind the maxilla. Upward pressure against the depressed portion usually suffices to elevate it satisfactorily (fig. 7). If this fails to maintain proper elevation, the antrum may be packed or the fragments may be wired in place through drill holes at the frontal attachment (Gill<sup>4</sup>).

**Maxillary Fractures.**—The preparation, adjustment and proper fitting of jaw splints for maxillary fractures requires a special technic and equipment not always available. For the surgeon not versed in this method, Federspiel's<sup>6</sup> technic provides a simple and

Fig. 7.—Author's method of elevating depressed malar by means of antrum trocar or other strong curved instrument. This method is simple and efficient in most cases.

satisfactory alternative. A No. 12 gage, preferably half-round, steel wire is firmly attached to the teeth of the upper arch. Brass fracture wire is then looped around

Fig. 8.—Federspiel's method of elevating fractured maxillae. Arch bar wired firmly to the upper teeth and traction wires attached in the bicuspid region and then passed through the cheek to head band. (Courtesy of Dr. Federspiel.)

this wire in the bicuspid region on each side (fig. 8). The ends of these wires are then threaded on a large curved needle and passed through the cheek just above the malar bone on each side. A plaster head cast with

4. Gill, W. D.: Fractures of Facial Bones, South. M. J. 27:197 (March) 1934.

5. Shea, J. J.: The Management of Fractures Involving the Paranasal Sinuses, J. A. M. A. 96:418 (Feb. 7) 1931.

6. Federspiel, M. N.: Treatment of Fractured Maxillae, Wisconsin M. J. 33:561 (Aug.) 1934.

coat-hanger wire attachments embedded in the plaster is next applied. The maxillae are then forced upward into proper position and maintained there by joining the ends of the brass wire to the attachments on the head cap. This method permits cleansing of the mouth and an accurate adjustment of the upward traction on the maxilla. This method obviates the necessity of

Fig. 9.—Guest-passenger injury. Fractured nose deviated to left. Fractured right malar bone, maxilla and mandible. Typical treatment. Head cast with forehead binding post and coat-hanger side wires; nasal fracture held over to right by author's nasal splint; maxillae held up by wires through cheeks to arch bar on teeth; malar bone elevated by author's method and held up by lateral pad held on by coat-hanger wire spring from anterior binding post. Arch bar on lower teeth; elastic traction to upper arch.

applying side arm splints, which may become dislodged. The small puncture marks through the skin of the cheek are scarcely discernible after a few weeks. I have never encountered serious infection around these wires (figs. 9 and 10).

Risdon<sup>7</sup> has suggested a simple method of applying an arch wire: A long wire is twisted firmly around each last molar. The wires from each side are then brought to the front and twisted together. These arch wires are then firmly wired to all teeth of the upper jaw. The traction wires are then attached to this wire arch as described.

Edentulous fractured maxillae may be treated in the same manner by drilling holes between the teeth of the denture and attaching traction wires to the artificial teeth.

**Mandibular Fractures.**—The intermaxillary loop method of wiring is the best method in the absence, of course, of associated maxillary fracture. When both jaws have been fractured, the maxilla is treated by Federspiel's method. After fixation of the maxilla, an arch bar is wired to the mandible; elastic traction is then applied between them. Bands cut from a quarter inch gum rubber tube serve the purpose nicely.

In fractures of the necks of the condyles associated with serious respiratory difficulties, traction wires are fixed to the cuspid region of the lower arch bar and passed through the lower lip. The jaw is held forward by attaching these traction wires to an arch of wire extending from a plaster head cast or to some apparatus on the bed (fig. 1).

Anterior displacements of the mandibular angle or the posterior fragment are held back by silver wire looped through drill holes in the angle of the mandible. These wires are then attached to hooks embedded in a plaster head cast (Ivy) (fig. 10).

#### SEQUELAE

In spite of every precaution, infections as well as other complications may supervene and make immediate surgical treatment impossible. Scars, crushed facial bones, loss of eyebrows, ears and nose—all such disfigurements require subsequent correction if the victim is to take his place again in society. Plastic procedures should not be undertaken, however, until the lapse of two months after every vestige of infection has disappeared. To intervene prematurely in these cases is to court disaster.

Old scars should be excised and resutured with subcuticular stitches as described (fig. 4). Depressions of the nose, forehead or malar prominences should be built up with rib cartilage transplants. Before applying the cartilage transplant, one should make a lead model made from a plaster impression of the face. At the operation, the cartilage should be trimmed to fit the depression on the sterilized lead model. This insures greater accuracy in restoring the normal contour.

Severed noses may be replaced by one of several well known plastic procedures. It is important that the skin to be transplanted should match the integument of the face in both color and texture. In women, the forehead flap method is most satisfactory. The resultant forehead scar can easily be concealed by the hair dress. In man, I prefer to use the skin beneath

Fig. 10.—Fractured malar bone, maxilla and left angle of mandible with marked overriding of posterior fragment of mandible. Treatment: Malar raised; arch bar and wires on maxilla; drill hole through angle of mandible and wire loop through bone; elastic traction from wire to hook on head cast to correct the overriding of posterior fragment.

the ear and overlying the sternocleidomastoid muscle.<sup>8</sup> This is brought to the face by way of a tube pedicle. Skin derived from this source is thin, flexible and practically hairless; in color and texture it closely matches the skin of the face.

7. Risdon, F.: Personal communication to the author.

address at each visit, states the probable duration of the illness, and whether the insured can work or not. At the final visit the physician must note the date at which work can be resumed. The diagnosis should never be written on the illness certificate and the latter must never be retained by the physician. No illness blank is required in emergency cases, but the insured must apply to the *caisse* for one as soon as possible after the first visit.

A special form of illness blank must be filled out by a surgeon or other specialist who will note the services rendered and the fees paid by the insured.

The insured can be hospitalized only in an institution that has a contract with the social insurance organization, and notice of such hospitalization must be immediately sent to the local *caisse* or disbursing bureau. If the hospital is one that has not made a contract, the *per diem* allowance to the insured will be equal only to that granted for care at the patient's domicile. A convalescent period shall not exceed seven days and can be paid for by the *caisse* only after written notice has been sent by the attending physician and after the medical controller of the local *caisse* has confirmed the necessity of such a period of convalescence. If a medical consultant is needed, the attending physician must specify this in a letter to the *caisse*.

The insured must pay the physician directly before the former can receive any remuneration from the *caisse*. The attending physician, specialist or surgeon must specify on the illness certificate that all fees have been paid and that all services have been rendered personally. On presentation of such a blank, duly signed by the medical attendant at the termination of the illness, to the *caisse*, the insured will be reimbursed. In case the insured cannot pay for medical services before being paid by the *caisse*, the latter can arrange to advance the fees if it considers that the individual merits such an advance.

5. A "treatment blank" is to be filled out by the attending physician and sent to the *caisses* with the "illness certificate" whenever therapeutic measures are necessary involving (a) a costly series of treatments, (b) consultations or numerous visits by the attending physician, (c) minor surgical procedures, (d) services of surgeons, specialists and orthopedic or dental apparatus, (e) hospitalization, (f) stay at watering places or (g) unusually expensive medication. Whenever ordinary prescriptions are given to the insured, a copy of each must be written on special forms.

6. The *caisses* have the rights through their medical supervisors to control the treatment of the insured, it being understood that professional secrecy, so far as the *caisse* is concerned, shall be maintained by the supervisor. The latter must examine the insured in the presence of the attending physician, except in cases in which the insured must be sent away from his own community. The supervisor is supposed not to criticize the treatment in the presence of the patient, but neglect of this requirement has resulted in a number of complaints being made to the *caisses* through the medium of the syndicates, who act as guardians of the interests of their members. The insured can refuse to be examined except in presence of the physician. The expense of all control examinations is paid by the *caisses*. The insured has the right to appeal from the decision of a medical supervisor.

7. The fees charged for medical services to the insured are those which were current in July 1930. Various attempts to raise these have been unsuccessful. If the attending physician is obliged to treat several members of the same family, each one must have a sickness certificate filled out, even for a single consultation. A visit to more than one sick insured person in a single family is considered as being entitled to payment for only one visit, the remainder being marked on the sickness blank as "gratuitous service."

8. The insured has the privilege of changing his medical attendant without notifying the *caisse* or asking for another

illness certificate, the second and subsequent attending physicians being obliged to use the same form. The insured must notify the local *caisse* before leaving the community in which the illness has occurred.

If a given illness lasts more than six months, the reimbursements cease automatically unless the insured is given an invalidity pension or is unable to obtain it. Any relapse that takes place within the two months subsequent to apparent recovery is considered as a part of the original illness, but the six months indemnity applies to both the latter and any relapse.

In case of a relapse after two months of apparent recovery, such relapse can benefit from the six months period granted the primary illness, but the apparent recovery must have been noted on the illness certificate.

In the case of an illness occurring which is different from that for which the original illness certificate was granted, the six months period of indemnity begins from the date of notification (to the *caisse*) of such an independent illness.

9. All pensioned individuals, if they receive salaries within the limits referred to in paragraph 2, have the right to receive indemnity from the *caisse* for every illness or injury not related to that for which they are receiving a pension. Indigents are cared for at the expense of the *caisses* at an average of 16 francs (80 cents) a visit. The attending physician must notify the *caisse* within three days after his first visit.

10. In the majority of the *caisses* in the department of the Seine the insured is reimbursed at the rate of 12 francs (60 cents) for each office visit to the physician and 2 francs additional for each house visit. Minor and major surgical procedures, for normal and pathologic deliveries, are reimbursed according to a fee table arranged between the syndicates and the departmental *caisses*. There has been much complaint as to the inadequacy of such fees. As to prescriptions for which the insured has paid less than 25 francs, the *caisses* allow 80 per cent, and for those above such sum only 60 per cent. All special drugs are paid for at the rate of 80 per cent. The same is true of all laboratory examinations.

#### Treatment of Hypochloremia and Preoperative Rechloridation

The effort to bring the sodium chloride content of the blood to its normal percentage is now termed "rechloridation." A contribution to the question appears in the September 1936 *Journal de chirurgie* by two Geneva surgeons, Drs. Mach and Sciclounoff. They emphasize the necessity of treating a hypochloremia before operation, because it increases after any intervention to such an extent as to give rise to alarming symptoms. The treatment of a hypochloremia preoperatively is not so simple a task as it would appear, because it is difficult to evaluate the degree of dechloridation, to know how much sodium chloride to give and its effect on the hypochloremia, on the percentage of chlorine in the tissues, on renal function and on the power of concentration. The authors first studied the variations of the normal chloremia during the minutes following the intravenous injection of the saline solution. When 8 Gm. of sodium chloride is given in a 20 per cent solution intravenously, the percentage of chlorine in the blood is raised to 0.5 Gm. per hundred cubic centimeters during the first minute following the injection and returns to the normal percentage at the end of an hour. A hydremia does not explain the drop of the transitory hyperchloremia. The same is true of the slight elimination of sodium chloride in the urine, bile and gastric juice; hence the authors, as the result of their previous studies, believe that the salt must be fixed by the tissues.

In the second part of this research, the variation of the chloremia when saline solutions are injected daily was studied. Instead of an 8 Gm. dose of sodium chloride, a larger amount, 12 Gm., was given daily to four patients who had a marked sodium chloride deficiency in the blood; i. e., a hypochloremia.

The resultant artificially produced hyperchloremia required a longer period before returning to the normal percentage of sodium chloride in the blood. This shows that a preoperative rechloridation necessitates the daily slow intravenous administration of sodium chloride over a number of days (from ten to twelve).

### BERLIN

(From Our Regular Correspondent)

Feb. 23, 1937.

#### The Development of the Influenza Wave in Germany

The onset of an influenza epidemic took place in Germany during November 1936. The disease spread rapidly from the beginning of December, reached its highest point shortly before Christmas and subsequently subsided. From observation of statistics for the last ten years the influenza epidemic would not have been expected before the end of this winter. The next few weeks will disclose whether a second eruption of the disease is to take place or whether the anticipated late winter peak will be lacking following this unusual early winter peak. The highest influenza mortality of any large city was reported from Berlin; there from the end of November to the end of December 1936 the rate was 3.2 fatal cases weekly per hundred thousand of population. The age distribution of the Berlin population, particularly unfavorable from the standpoint of health, must be considered responsible for this high figure. Moreover, special statistical reports from a large proportion of the hospitals indicate that virtually every city had its own particular type of epidemic. The general impression conveyed by the sum total of data is that the influenza was less prevalent in the northwestern section of the reich than in Berlin and northern Germany. So far as the epidemic may be said to have taken a certain direction, it seemed to move from the north and northeast toward the south and southwest.

#### Further Investigation of the Klein Cancer Reaction

In a recent account of experimentation with the Klein cancer reaction at various clinics (THE JOURNAL Oct. 17, 1936, p. 1315) it was stated that, pending further investigation and discussion, any final evaluation of the procedure should be withheld. To the previously mentioned favorable opinions only those emanating from the medical and surgical clinics at Marburg may be added. Klapp, professor of surgery, reports that the "blind" test showed itself 96 per cent accurate when applied to a group of fifty-two cases. Those "disturbing factors" mentioned in the previous letter were present among these cases. Klapp believes, nevertheless, that detection of latent carcinoma and introduction of early treatment are made possible by the Klein test. As the result of experimentation at the Marburg medical clinic, six of seven patients presenting certain cancer showed positive reactions; the blood of ninety out of ninety-eight patients who presented no malignant neoplasms reacted negatively; namely, eight of the ninety-eight results were incorrect. The proportion of correct results was accordingly in this instance 91.2 per cent, a figure that corresponds with the norm of accuracy as determined by Klein himself. The test yielded incorrect, that is, negative, results when applied to seven cancer patients whose condition was complicated by disturbing factors. The reactions of forty cancer-free patients in whom disturbing factors were present were correct (negative) in seventeen cases and incorrect (positive) in twenty-three cases. In this instance the percentage of accurate results was only 42.5, yet despite this poor showing the Marburg people decided on the basis of these figures that the Klein reaction should be regarded as of incontestable clinical worth.

Another recent development, however, has been an increase in the number of unfavorable reports on the Klein test. The surgical clinic at Göttingen regards a ratio of 56 per cent correct to 44 per cent incorrect results as distinctly unsatisfactory. At the Heidelberg surgical clinic, 88 per cent of the

reactions of an open group were correct, but for a "blind" group only 68 per cent of the reactions were consistent. The surgical clinic of Freiburg-in-Breisgau reports that 60 per cent of the reactions were correct if no disturbing factors were present. Professor Simon, director of the surgical section of the big hospital at Ludwigshafen-on-Rhine, has recently pointed out that the number of those disturbing factors which play so decisive a part in the evaluation of the Klein reaction, far from being reducible, has rather tended steadily to increase. Among these factors are now included such conditions as obstipation, hernias and subacidity. The latest investigation of the test has been undertaken at the surgical clinic of Zurich, Switzerland. Dr. Fehr, head physician there, determined correct reactions in only 64.6 per cent of 274 utilizable patients tested. Even worse were the results when cases presenting tumors of histologically proved malignancy were tested; in only 30 per cent was the Klein diagnosis correct.

#### When Is Tonsillectomy Indicated?

Dr. Vogel, head physician of the Berlin University throat clinic, recently defined his position before the Berlin Medical Society with regard to the question When is tonsillectomy indicated? He emphasized that the much criticized performance of tonsillectomy was nevertheless clearly justifiable in the absence of any better means of treating chronically diseased tonsils. The operation must of course be unequivocally indicated. Tonsillectomies should be performed in chronic tonsillitis if the patient is an adult and if the masses of bacteria in the lacunae, having no free outlet, cause a retention of pus within the organism. Besides the squeezing out and drainage of the tonsils, subjection of the throat to light baths should be considered in the first rank of conservative procedures. Clinically, one frequently observes in chronic tonsillitis the picture of general fatigability, depressive ill humor, tendency to cardiac palpitations, general rheumatic complaints, digestive disturbances and above all a persisting susceptibility to colds. Other foci of infection, dental granulomas for example, should be carefully excluded. If repeated angina simplex and abscess have appeared, a timely removal is unconditionally indicated. If the tonsils are to be removed, a radical extirpation is necessary; no certain success is to be expected from mere incision or partial removal.

Dr. Vogel considers roentgen irradiation of the tonsils a useless procedure, as tonsillitis does not represent a hypertrophy of the glandular tissue but chiefly an atrophy of the lymphatic tissue and a hyperplasia of the connective tissue. Tonsillectomy should be less quickly resorted to if the patient is a child. A tonsillar abscess should only be incised, for in this condition, on account of the danger of septic bacterial invasion of the lymphatic and blood streams, tonsillectomy cannot be regarded as a harmless intervention. Dr. Vogel has seldom observed complications following tonsillectomy; genuine impairments of function are unknown and an increased susceptibility to infections has not been proved to exist. Most of the collected data on the subject sound favorable.

## Marriages

JOHN K. STALVEY JR., Conway, S. C., to Miss Charlotte Barbara Reynolds of Charleston, in December 1936.

WILLIAM ALLISON STEM, Chattanooga, Tenn., to Miss Mary Lucille Converse of Memphis, Tenn., Dec. 26, 1936.

GUS ADOLPHUS RUSH JR., Meridian, Miss., to Miss Helen Virginia Arline of Atlanta, Ga., in January.

BERNARD E. MALSTROM to Miss Opal Gordon, both of Decatur, Ill., in Canton, Nov. 19, 1936.

THURLOW HEMSWORTH PELTON to Miss Virginia Noble, both of Westfield, N. J., Dec. 20, 1936.

DIEDRICH L. OLTMAN, East Moline, Ill., to Miss Myrtle A. Kenney, Dec. 19, 1936.

## HOSPITALS OF THE UNITED STATES

Again, for the twenty-seventh consecutive year, a net increase of more than 20,000 hospital beds has occurred. The average annual increase in hospital facilities over that period has been 25,024 beds. The total number of patients treated in hospitals in 1936 reached 8,646,885, and the total patient days 332,516,856. Patients were received for hospital care at the rate of sixteen to the minute, and 831,500 babies were born in hospitals during the year. These figures make us realize the extent to which the practice of medicine is being transferred to hospitals.

Ninety-seven per cent of all the registered hospitals in the United States responded to the census, and the information which they supplied gave evidences of a degree of completeness and accuracy never before obtained in such a survey. The response represented more than 99.5 per cent of the hospital capacity in the United States.

Acknowledgment is made here of the fine cooperation which most of the hospitals expressed by promptly and efficiently filling out and returning the questionnaire.

## TUBERCULOSIS OF THE SPINE

The gradual disappearance of the "hunchback" has been one of the most obvious signs that the education of the public with regard to tuberculosis, combined with modern preventive and therapeutic measures, has borne precious fruit. Earlier diagnosis and improved surgical methods of treatment have assisted in reducing the number of permanent cripples. Schneider and Van Hecke<sup>1</sup> estimated that one third of the cases of bone tuberculosis are situated in the spine. They noted the poor general physical condition of these patients and the high incidence of complications, such as pulmonary tuberculosis, abscesses, draining sinuses, paraplegia, and

involvement of other bones. The general symptoms were anorexia, anemia, rapid pulse, loss of weight and evening rise of temperature, the local ones pain (local or referred), tenderness, rigidity (muscle spasm), deformity and symptoms due to pressure on the spinal nerves. A recent pathologic and roentgenologic study<sup>2</sup> of tuberculous spines emphasizes that the primary site of the infection is in the body of the vertebra and that the intervertebral disk is relatively resistant to involvement early in the course of the disease. The structure of the disk varies with age but, in the adult, blood vessels are not present. The vertebral bodies are richly supplied with nutrient arteries and thus afford a suitable nidus for the hematogenous implant from a pulmonary or alimentary lesion, the common primary foci. Necrosis of the spongiosa and cortex occurs, with collapse and partial absorption of the bone. Microscopic sections may or may not show typical tubercles. The narrowing of the disk line sometimes seen roentgenologically in early tuberculous spondylitis is considered by the authors to be due to escape of all or part of the semi-fluid nuclear material of the nucleus palposus, the result of damage to the cartilage plate by trauma or disease. The investigators found no instance of direct spread of the tuberculous process through the intervertebral disks, but extension beneath the paravertebral ligament occurred frequently.

In contrast to tuberculosis of the spine, pyogenic vertebral osteomyelitis is often primary in the arch or vertebral appendages, and early destruction of the intervertebral disk occurs. Extension of the process takes place directly through the intervertebral disk from centrum to centrum, and regeneration of bone begins when the acute infection subsides. When vertebral tuberculosis is complicated by pyogenic infection, the patient's chances of recovery are greatly lessened. The cold abscess does not heal, and amyloidosis and death frequently follow. The pathologic changes in the mixed infection may be typical of tuberculosis, of pyogenic osteomyelitis or of a combination of the two.

The mode of extension of the tuberculous process by infiltration of pus beneath the paravertebral ligament has been observed by Dubrow,<sup>3</sup> Sever<sup>4</sup> and Rigler, Ude and Hanson,<sup>5</sup> who have noted the frequent occurrence of paravertebral abscess as a complication in tuberculous spondylitis. In roentgenologic appearance it is a bilateral, fusiform or spindle-shaped area of increased density in the vicinity of the spine, which is often obscured by the shadow of the heart. Its detection is of the greatest importance in making an early diagnosis, before disease of the bone can be demonstrated roentgenologically, and in determining the extent of the tuberculous process and the prognosis.

## Deaths

**Charles Evelyn Rynd**, Brooklyn; Johns Hopkins University School of Medicine, Baltimore, 1911; formerly clinical professor of obstetrics and gynecology at the Long Island College Hospital; fellow of the American College of Surgeons; served during the World War; aged 53; attending gynecologist and obstetrician and director of gynecology and obstetrics, Kings County Hospital; on the staff of the Midwood Hospital, where he died, January 12, of chronic nephritis, hypertension and uremia.

**Francis Joseph Nash** ☉ Boston; Tufts College Medical School, Boston, 1919; member of the New England Obstetrical and Gynecological Society; fellow of the American College of Surgeons; visiting surgeon to the Carney Hospital; on the staffs of the Faulkner and St. Margaret's hospitals and the New England Hospital for Women and Children; aged 41; died, January 11, of cardiorenal disease.

**Peter Herman Schroeder**, Davenport, Iowa; State University of Iowa College of Medicine, Iowa City, 1904; member of the Iowa State Medical Society; for many years medical inspector for local schools; served during the World War; member of the Associated Anesthetists of the United States and Canada; aged 57; on the staff of St. Luke's Hospital, where he died, January 19, of coronary occlusion.

**Edward Henry Trowbridge** ☉ Worcester, Mass.; Medical School of Maine, Portland, 1884; fellow of the American College of Surgeons; member of the American Urological Association; formerly chairman of the health department and member of the school board; aged 80; on the staffs of the Worcester City Hospital and the Harvard Private Hospital, where he died, January 20.

**Henry Earl Fraser** ☉ Major, M. C., U. S. Army, Fort Davis, Canal Zone; Vanderbilt University School of Medicine, Nashville, Tenn., 1915; member of the Medical Association of Georgia; served during the World War; was commissioned a first lieutenant in the medical corps of the regular army in 1918 and was made a major in 1929; aged 49; died, January 16, of coronary occlusion.

**Marcus Lunsford Dillon**, Lewisburg, W. Va.; Maryland Medical College, Baltimore, 1908; member of the West Virginia State Medical Association; fellow of the American College of Surgeons; served during the World War; formerly on the staffs of the Kanawha Valley, McMillan, Mountain State and New Charleston General hospitals, Charleston; aged 56; died, January 31.

**Frank Jesse Otis Jr.**, Boston; Harvard University Medical School, Boston, 1931; aged 31; flight surgeon, U. S. Army Reserve, first lieutenant 101st Observation Squadron, Quiet Birdmen 2085 A; intern at the Boston City Hospital; died, January 11, when the plane he was piloting fell in the Illinois River near Hennepin, Ill., as he was en route to visit his parents in Moline, Ill.

**Albert Hawes Cordier**, Kansas City, Mo.; University of Louisville (Ky.) Medical Department, 1881; Bellevue Hospital Medical College, New York, 1884; an affiliate Fellow of the American Medical Association; formerly professor of principles and practice of surgery and clinical surgery at the University Medical College, Kansas City; aged 78; died, January 23, of pneumonia.

**George Charles Diekman**, New York; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1891; formerly instructor, professor and head of the department of pharmacy and associate dean, Columbia University College of Pharmacy; member of the state board of pharmacy, and for three years its president; aged 74; died, January 30.

**John Henry Stearns**, Delaware Water Gap, Pa.; Medico-Chirurgical College of Philadelphia, 1896; member of the Medical Society of the State of Pennsylvania; served during the World War; for many years county medical director; on the staff of the Easton (Pa.) Hospital; aged 64; died, January 17, of coronary thrombosis.

**James Thomas Tibbetts**, Mineola, N. Y.; Long Island College Hospital, Brooklyn, 1890; member of the Medical Society of the State of New York; examining physician for the public schools of Mineola; on the staff of the Nassau Hospital; aged 82; died, January 16, of chronic myocarditis and cerebral thrombosis.

**Leonard Hart** ☉ Meridian, Miss.; Columbia University College of Physicians and Surgeons, New York, 1906; served

during the World War; on the staff of Rush Infirmary; medical consultant in tuberculosis for the Lauderdale County Health Department; aged 54; died, January 19, of angina pectoris.

**Clarence Eugene Ordway** ☉ Winchester, Mass.; Harvard University Medical School, Boston, 1904; member of the New England Obstetrical and Gynecological Society; for some years had been chief of the staff of the Winchester Hospital; aged 58; died, January 5, of coronary thrombosis.

**David Ewing Evans**, Harrison, Ark.; Arkansas Industrial University Medical Department, Little Rock, 1896; member of the Arkansas Medical Society; city and county health officer; formerly county coroner and mayor of Harrison; aged 81; died, January 10, of cerebral hemorrhage.

**Ferd De Forrest Streeter** ☉ Rochester, N. Y.; University of Vermont College of Medicine, Burlington, 1912; member of the American Psychiatric Association; on the staff of the Rochester State Hospital; aged 52; died, January 20, in the Strong Memorial Hospital, of cellulitis.

**Earl Wadsworth Wilcox** ☉ Norwich, N. Y.; Albany Medical College, 1894; past president of the Chenango County Medical Society; county coroner; aged 65; on the staff of the Chenango Memorial Hospital, where he died, January 6, of chronic nephritis and heart disease.

**Frank Edward Schubmehl**, Lynn, Mass.; Boston University School of Medicine, 1898; member of the Massachusetts Medical Society; aged 69; died, January 5, in the New England Deaconess Hospital, Boston, of cerebral hemorrhage, diabetes mellitus and auricular fibrillation.

**John Rainey Parker** ☉ Berryville, Ark.; University College of Medicine, Richmond, Va., 1901; past president and secretary of the Carroll County Medical Society; owner of the Berryville Hospital; aged 59; died, January 12, of complications resulting from bronchopneumonia.

**James Joseph Lynch**, Boston; Harvard University Medical School, Boston, 1919; member of the New England Obstetrical and Gynecological Society; on the staff of St. Elizabeth's Hospital; aged 42; died, January 9, in the Boston City Hospital, of acute dilatation of the heart.

**John Adams Mather** ☉ Greenfield, Mass.; Baltimore Medical College, 1902; member of the New England Roentgen Ray Society; served during the World War; on the staff of the Franklin County Hospital; aged 60; died, January 16, of angina pectoris and arteriosclerosis.

**Albert Edward Bower**, Camp Hill, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1898; member of the Medical Society of the State of Pennsylvania; aged 64; died, January 24, in a hospital at Harrisburg, of carcinoma of the rectum.

**Lawrence Kilpatrick Dugan**, Delanson, N. Y.; Albany Medical College, 1900; medical inspector of the Delanson high school, health officer of the town of Duaneburg; aged 62; died, January 23, of suffocation and burns received when his home caught fire.

**Drury Orestes McCrary**, Mobile, Ala.; Pulte Medical College, Cincinnati, 1896; member of the Medical Association of the State of Alabama; on the staff of the Providence Infirmary; aged 67; died, January 22, of hypertrophy of the prostate.

**Frederick Reynolds Ford** ☉ Utica, N. Y.; Johns Hopkins University School of Medicine, Baltimore, 1905; on the staffs of the Masonic Soldiers and Sailors Memorial Hospital and St. Luke's Hospital; aged 57; died, January 25, of angina pectoris.

**William Floyd Shaw**, Voorheesville, N. Y.; University of the City of New York Medical Department, 1885; member of the Medical Society of the State of New York; aged 73; died, January 10, of coronary sclerosis and cerebral hemorrhage.

**Horace Ware Given**, Philadelphia; Medico-Chirurgical College of Philadelphia, 1912; member of the Medical Society of the State of Pennsylvania; aged 61; died January 22, in the Cooper Hospital, Camden, N. J., of coronary thrombosis.

**Bascomb B. Dawson** ☉ Ada, Okla.; Gate City Medical College, Dallas, Texas, 1908; formerly secretary of the Pontotoc County Medical Society; on the staff of Breco's Memorial Hospital; aged 62; died, Dec. 24, 1936.

**Duncan Andrew Murray**, River John, N. S., Canada; McGill University Faculty of Medicine, Montreal, Que., Canada, 1889; aged 73; died, Dec. 28, 1936.

**Leon Herbert Dudley** ☉ Morris, N. Y.; Syracuse University College of Medicine, 1925; aged 38; died, January 14, in the Parshall Private Hospital, Oneonta.

## OVERCROWDING AND OVERBUILDING OF HOSPITALS

This year hospitals in the United States were asked to state their rated capacity, meaning the number of patients which the hospital was intended to accommodate. One of the conditions revealed was overcrowding in some state mental hospitals. Owing to lack of funds to provide quarters and room for equipment and facilities, there has been overcrowding of the living space and particularly of sleeping quarters. Beds are placed in corridors, on porches and in passageways. Beds are found touching head to head or even side to side where there is not sufficient space.

The statistical data on page 1035 in this issue of *THE JOURNAL* tell how many hospitals have been found in each relative degree of overcrowding. The information is presented for those who may make use of it to hasten relief of the discomfort and retardation that result from overcrowding. Letters from state hospital commissions, welfare departments and superintendents have pointed out the higher rate of recovery and discharge of patients from state mental hospitals where overcrowded conditions have been relieved. Some states are receiving appropriations annually sufficient to cope with the number of new patients added to the population of the institution each year. Other states are in process of building sufficient structures to achieve that desirable purpose, and still other states have not yet established appropriations sufficient to cope with their responsibilities to the increasing number of their mentally ill citizens.

The general hospitals responded with surprising completeness to the question added this year as to their rated capacity, or the number of patients which their buildings were intended to accommodate. Conditions there, however, are exactly opposite to those in the state mental hospitals. An analysis of the situation in general hospitals has not been possible. A cursory examination of the reported rated capacity shown in the list of registered hospitals readily demonstrates a general condition of overbuilding rather than overcrowding. General hospitals have been found with from 30 to 50 per cent of their beds unoccupied, but actually many of them have large spaces, whole floors, sometimes entire buildings that have never been occupied or even furnished; and this is observed quite often in communities where ambitious building campaigns are now under way.

The high rate of overbuilding of general hospitals has been reported by voluntary organizations, including churches and a good many city general hospitals. The overbuilding of hospitals in any community is a tax on that community whether the hospital is supported by taxes, by endowments, by contributions or, in fact, by patients. However, the cost of overbuilding in dollars is not the greatest concern. Provision of more hospital facilities than are really needed for

the sick and injured encourages an effort to make use of them—in other words, of overhospitalization of patients.

The proper accommodation of some patients with mental disease and of some with tuberculosis in general hospitals may aid in economic utilization of the oversupply of beds. Figures presented in this issue of *THE JOURNAL* would seem to encourage this movement.

---

## THE SEARCH FOR NEW INSECTICIDES

Lead arsenate has been for years the main reliance in the control of insects that prey on food crops. As the product is poisonous a significant amount of residue from its use on fruits and vegetables is deleterious to health. The United States Department of Agriculture has been endeavoring to discover a more nearly ideal insecticide. According to the chief of the Bureau of Entomology and Plant Quarantine, Lee A. Strong, the most promising discovery which the department has made is a sulfur compound called phenothiazine. This new product, which is easily prepared by combining sulfur and diphenylamine, has been tested in large scale field tests, which, although highly encouraging, showed the need for more study. Phenothiazine will control the codling moth, the chief insect pest affecting the apples in the Northwest, much better than will lead arsenate, and it leaves a residue that is less likely than lead arsenate to injure the consumers of the treated food products. The main objection to using phenothiazine in the orchards is its effect on the skin of those who handle it. The orchard men who work with it are afflicted with what looks and feels like a severe sunburn; and sometimes the apples are paler than the untreated fruit. Phenothiazine has given rather disappointing results in the Middle West and in the East, but sufficient satisfactory control work has been reported to justify a continuation of the study.

Nicotine has also been tried as a substitute for lead arsenate. The research has been directed chiefly toward the combination of nicotine with some other substance to produce a product that will remain poisonous for some time. A combination of nicotine with soap or lime sulfur mixture is effective against soft-bodied insects, but not so against the codling moth, which must be made to swallow the poison. Bentonite, a natural clay found in the Far West, will unite with nicotine when mixed with a salt of nicotine dissolved in water. When nicotine-bentonite combinations are sprayed on foliage, the material dries to a fine dust which kills the larvae of the codling moth. This combination would seem to be especially useful in spraying early apples. The Department of Agriculture has been testing a combination of nicotine with peat. Nicotine-peat contains up to 13 per cent of nicotine in a form that will not wash off sprayed apples or foliage. What this new material will do under practical orchard conditions, however, remains to be seen.

## Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

### FRACTURE OF NECK OF FEMUR

To the Editor:—I have applied a double plaster-of-paris spica on a woman, aged 62, with an intracapsular fracture of the neck of the left femur and would like you to answer the following questions: 1. How long should the cast be left on? 2. If x-ray examination shows nonunion after this period, what is the next procedure? 3. What can be done to facilitate union? 4. After a sufficient period has elapsed with nonunion, what orthopedic appliances, if any, are used? Kindly omit name.

M.D., New York.

ANSWER.—Intracapsular fractures of the neck of the femur have been designated as the "unsolved fracture" by Speed and the "problem fracture" by Moorhead. These terms are suggestive of the unsatisfactory results that have been obtained, regardless of the method of treatment. Accurate reduction is essential. The position of the fragments should be checked by lateral as well as by anteroposterior roentgenograms of the femoral neck. The direction of the fracture line in its relation to the long axis of the femur and the vitality of the proximal fragment are most important factors to be considered in giving a prognosis.

Fractures of the femoral neck heal by endosteal callus formation rather than by subperiosteal deposition of new bone. Because of this, bony union cannot be demonstrated at the site of fracture until trabeculation has been reestablished.

1. The cast should remain in place from four to five months. This should be followed by the prolonged use of a caliper brace.

2. If definite nonunion is demonstrable by roentgenograms with the push and pull technic, several courses are open to the surgeon. Fixation of the fragments by the insertion of metal pins or wire, or autogenous bone grafting may be indicated, depending on the facilities available and the skill of the operator. Subtrochanteric osteotomy is employed to correct the line of weight bearing. Reconstruction operations of the Brackett or Whitman type are useful in the reestablishment of bone to bone weight bearing.

3. Measures directed toward the maintenance of the patient's general health are indicated. A good general diet rich in calcium is indicated even though the relationship between calcium intake and fracture healing is indefinite. Passive flexion of the knee made possible by bivalving the lower portion of the cast will prevent troublesome contractures of the quadriceps femoris.

4. External appliances in cases of nonunion are of but little aid in reestablishing weight bearing in this type of fracture.

### SAFETY AND UTILITY OF FLUOROSCOPY

To the Editor:—Can fluoroscopy be made absolutely safe for the examining physician? If so, under what conditions? Is there any danger from the fluoroscope when the apparatus is in the same room in which the physician remains continuously for several hours daily, assuring that the machine is not in use? And is there any danger, if used for about two minutes (from five to ten times) each examination, daily? Kindly suggest one or two elementary books on fluoroscopy. Please omit name.

M.D., New York.

ANSWER.—Fluoroscopy cannot be made absolutely safe for anybody without elaborate apparatus. Such apparatus has been devised in a few institutions. Belot of Paris has described apparatus for fluoroscopy that is as nearly safe as it is possible to make such an instrument. The patient is completely shut off from the physician by lead-protected walls. Literally, the patient stands in another room, the only communication being the fluoroscopic screen, which is incorporated into one of the walls. Such apparatus completely prohibits the use of screen-guided manipulation with the gloved hand or wood palpator, a type of palpation that is necessary to satisfactory fluoroscopic examination.

Of course, there is no danger from the fluoroscope when the apparatus is not in use.

No one can suppose for a moment that fluoroscopy gives adequate information except in a rather limited field, as for instance in the examination of the chest. The fluoroscope gives

information regarding the excursion of the diaphragm, the relative height of the diaphragm, the condition of the phrenic angles, the mobility of the heart in relation to the diaphragm, the esophagus and gross lesions of the chest. It is impossible for even the most expert and the most experienced to see as much tissue detail in the fluoroscope as can be seen on the films. The fluoroscope can never take the place of the films. It does, however, supplement the film study in an indispensable manner. Fluoroscopy gives information as regards the size of the heart and the movements of the walls of the different chambers of the heart. Pulsations of the aorta or vascular tumors can sometimes be noted; although the absence of pulsations does not mean that a certain shadow is not due to a vascular tumor, and the presence of a pulsation does not mean that the tumor is of the aorta; for transmitted pulsations are difficult to differentiate from intrinsic pulsations.

In English, elementary books are those by Holmes and Rugles (Roentgen Interpretation, published by Lea & Febiger) and Harrison's recent Textbook of Roentgenology. There are no classic works on fluoroscopy alone, since fluoroscopy is only one phase of the roentgen study and the textbooks all deal with the full subject.

### TOXIC EFFECTS OF ERGOTAMINE TARTRATE USED IN MIGRAINE

To the Editor:—A white woman, aged 32, otherwise in good health, suffers from severe migraine. For the past six months she has been taking ergotamine tartrate 0.25 mg. subcutaneously, aborting the attacks completely. These sometimes come as often as twice a week. She has always suffered from cold hands and feet. For the past two months she has noticed mild numbness in her hands, particularly on awakening. Could there be any possibility of peripheral circulatory disturbance from the long continued use of the drug in this dosage, never more than two doses a week being given? Please omit name.

M.D., Alabama.

ANSWER.—There is a possibility of the production of ergotism from ergotamine. Substitution of some other therapy until the numbness has subsided, followed by cautious resumption of the ergotamine treatment and watching for recurrence of the symptom might clear up the question. Care must, of course, be taken to eliminate the disturbing influence of suggestion.

### INTRAMUSCULAR INJECTION INTO BUTTOCK

To the Editor:—I frequently have occasion to use intramuscular injections into the buttock, giving bismuth preparations in the treatment of syphilis, mercurials or liver. It seems that I have an unusual number of complaints of soreness for days and pain radiating down the leg, indicating some irritation of the sciatic nerve. I have conscientiously attempted to avoid this, without great success. I would appreciate it if you would advise me whether a proper technic renders these injections painless. If so, mine must be faulty. I would therefore request that you give me explicit directions for intramuscular injections into the buttocks with definite care as to the landmarks so that there may be no question as to the described area. Please omit name.

M.D., Washington.

ANSWER.—A certain amount of pain and the soreness following the giving of intramuscular injections in the hip may be due to the preparation employed. There are certain salts of mercury and bismuth that are rather irritating, for example mercuric salicylate or any one of the soluble mercurials such as biniodide, binbromide or bichloride. With most of the bismuth preparations there is little or no discomfort if the injection is made into the muscles, and there should be no difficulty in making this injection. One should simply divide the buttock into four quadrants and give the injection in the upper and outer quadrant always, being careful to palpate the area before the injection to see that one is not injecting an area that shows some induration. Employ a needle 1 1/4 inches long and of 22 gage for an aqueous solution or 21 gage for an oily suspension. A record syringe kept in alcohol may be employed, or a glass Luer syringe that may be sterilized is also suitable.

Have the patient stand on the leg opposite to the side to be injected, in order to have the muscles perfectly relaxed. It is sufficient for sterilization purposes to scrub the area thoroughly with some cotton and alcohol and then pull the skin downward from the area you wish to inject. Taking the syringe between the first two fingers and the thumb, with a wrist motion only, one should plunge the needle boldly into the muscles, not slowly push it in. All it requires is a stroke motion of the hand backward and then boldly forward from the wrist. Before the injection one should aspirate on the barrel of the syringe to be sure one has not penetrated an artery or vein. This is preferable to removing the syringe to see whether the blood will run from the needle, for with a negative suction of the syringe one has a better chance of discovering whether one has

A disadvantage of nicotine sprays is that they are expensive; furthermore, too many applications may injure foliage, and lead arsenate residues cannot be removed as readily if nicotine and oil have been used during part of the season.

The Department of Agriculture is investigating also the possibilities of pyrethrum as an insecticide. It is endeavoring to synthesize the insecticidal principles of pyrethrum, which now has to be imported into the United States from the Far East. The chemical formulas heretofore accepted for these insecticidal principles have recently been found to be incorrect, and the discovery of that mistake has given a turn to the research which may produce the results desired.

Out of these varied investigations by the Department of Agriculture probably will come a practical and efficient new insecticide. As yet, however, not one of the numerous products studied is recommended for general use.

## *Current Comment*

### EDUCATION OF HOSPITAL PERSONNEL

Managing hospitals is a complicated business, rendering a service to sick and injured persons. As the preparation of physicians involves education and practical training under supervision, so, one by one, the other types of personnel in the hospital will tend to be employed on the basis of schooling, experience and other measured qualifications. The public is gradually learning what to expect of hospitals. The best that is known in medical skill, technical aid and personal comfort should be available in every institution that calls itself a hospital. The encroachment of politics and greed in public hospitals is being rebuffed. The gradual improvement of hospital service will depend largely on the extent to which education of hospital executives and personnel approaches higher standards.

### ASSIGNMENT OF CREDIT FOR INTERNSHIPS AND RESIDENCIES

For a number of years the American Medical Association has assigned credit in its biographic files to all physicians serving appointments on the house staffs of approved hospitals. Blanks are forwarded to these institutions as a convenient means of submitting the names of interns and residents currently employed and those who have completed services during the previous twelve months period. Data are also included which state the medical school and date of graduation and the dates of commencement and termination of service. The importance of such a central registration system increases year by year, not only as a means of contributing to the value of the American Medical Directory but as a convenient means of reference to various agencies such as licensing boards, hospitals making appointments or promotions to higher house staff positions, and examining boards for specialty certification. In all such instances, additional recognition or credit depends on previous completion of an internship

in an approved hospital. Importance attaches especially to the receipt of accurate information from the hospitals. Verifying correspondence is necessary in many instances when claims of physicians and statements from institutions are at variance. There is, however, general appreciation of the value of such credit to house officers, and requests for confirmation or additional statements are cheerfully supplied. An additional advantage arises from the ability of the Association to follow up in all cases of incomplete services in an effort to determine whether these represent broken internship contracts. This procedure, with excellent cooperation from the deans of medical schools, has served to reduce the number of these troublesome episodes materially. If it is understood that an intern should make his investigation of an appointment before and not after he has accepted it, the problem will largely disappear.

### THE LEAGUE OF NATIONS AND WORLD HEALTH

Dr. Victor Heiser, author of "An American Doctor's Odyssey," in the course of his travels had ample opportunity to observe the development of the health activities of the League of Nations. The Health Organization of the League of Nations, he states in a recently published bulletin,<sup>1</sup> is not a superhealth agency nor does it undertake to apply health measures directly through its own agents, as does the Red Cross. It acts more as a clearing house, bringing together international groups that can deal effectively with a particular problem. Its specific benefits are already numerous and include material aid rendered in such problems as that facing Greece in 1928 resulting from war, pestilence and the influx of thousands of refugees. The work of the Health Organization of the League of Nations has been singularly free from many of the difficulties that have confronted other activities of the league. It has been able, therefore, to work effectively toward the following objectives: (1) the control of epidemics and other diseases and the collection and dissemination of epidemiologic data, (2) standardization of serums and biologic products, (3) unification of health statistics, (4) publication of health information, (5) interchanges of health officers, (6) cooperation with other League of Nations groups and international organizations, and (7) technical cooperation with health administrations of various countries. The part played by the league in the prevention of smallpox, cholera, typhoid, malaria, leprosy and syphilis is briefly touched on in Heiser's discussion. The necessity for epidemiologic intelligence to aid in the prompt suppression of epidemics was early demonstrated in the Russian-Polish situation of 1922. Further evidence of the importance of this assistance has since been shown on numerous occasions. The various and preferred methods of ship fumigation have been studied exhaustively by the league, and reviews of this subject have been prepared and distributed. One division of the Health Organization concerns the coordination of biologic research. The principal aim of this division is to

1. Heiser, Victor: Millions of Patients: What the League is Doing for the World's Health, League of Nations Association, Mid-West Office, Chicago, 1937.

entered a vessel. Following this the medication is slowly injected into the area. The needle and syringe as one, with one stroke, are removed and the area is well massaged with the cotton and alcohol that were previously employed for sterilizing purposes.

With this technic one should have no difficulty with the average preparation employed, but there are certain mercurial preparations especially that may cause some irritation, which cannot be attributed to the technic of the physician.

#### UNUSUAL INFECTION OF LEGS

*To the Editor:*—A woman, aged 34, always in good health, went to China as a missionary in 1923 and remained there almost continuously until 1932. During this time, in 1926, she developed what was called blood poisoning. Her temperature fluctuated between 103 and 105 F. for about six weeks. Among the first things noticed at that time was a red to purple slightly elevated ring about half an inch wide encircling the left ankle. This area ascended the leg from 1 to 2 inches a day until it reached her thigh and then descended on the right leg, disappearing again at the ankle. In 1931 she developed "malignant malaria," although as far as can be determined no positive laboratory examinations of any sort were made. Symptoms consisted of headaches, dizziness and backaches and a temperature fluctuation between 99 and 99.6 F. She states that the best relief she obtained was with intravenous injections of arsphenamine. She was sent back to her home in this country because of her poor health. She has been weak and tired since then. Frequent small superficial abscesses have developed which require about two weeks to heal, but she has not had one to obtain a culture from since I have seen her. The temperature fluctuates between 97 and 99.6. In 1932 she had a cholecystectomy; the gallbladder was stated to contain many stones and pus. Physical examination does not show anything of significance except the tenderness in the right upper quadrant, where she occasionally complains of pain. Her weight has remained between 116 and 124 pounds (53-56 Kg.), which is good for her size. The pulse varies between 80 and 116. Hemoglobin is 80 per cent; lymphocytes number 31 per cent, transitionals 1 per cent, eosinophils 2.5 per cent, neutrophils 65.5 per cent and basophils 0. The urine shows only an occasional pus cell; the reaction is alkaline; the specific gravity varies between 1.001 and 1.020. The Wassermann reaction and agglutination with *Brucella abortus* are negative. Blood smears are negative for malaria. The stools and urine have repeatedly been negative for typhoid and paratyphoid. The blood gave a flocculant but not granular sediment. The agglutination test with the typhoid bacillus was done on two occasions during the past month. She received typhoid-paratyphoid vaccine in 1923, 1928 and 1931. She is anxious to return to China but cannot until her health improves. I would appreciate any suggestions as to diagnosis, further laboratory procedures, and treatment. Please omit name and address. M.D., New York.

*ANSWER:*—Without more information about the conditions in this patient when the so-called blood poisoning developed in 1926, it would be useless to speculate as to the nature of the skin lesion on the legs. It is certainly not characteristic of filarial infections and, more likely, represented a streptococcal or staphylococcal infection; furthermore, the history of malaria in 1931 is unsupported by the positive identification of malarial organisms in the blood. Without such identification, the diagnosis is more than questionable. It is not stated at what city she lived in China, which might throw some light on this question of the nature of the malaria, if any. Arsphenamine and arsenic preparations would not have cured malaria. There is certainly a strong suspicion that the original bacterial infection of 1926 is still present. To settle this, a series of blood cultures ought to be taken daily for at least five days at a time when the temperature is at its maximum for the day. Such cultures should be taken on a variety of mediums, including brain broth, and should be kept for at least ten days before being discarded as negative. A careful gastro-intestinal x-ray series should be taken, together with visualization of the gallbladder and roentgenograms of the kidneys after the injection of a dye. A meticulous examination for foci of infection should be made, including very scrupulously the teeth, pelvis and rectum. Urine cultures of a catheterized specimen should be made at least twice, as a bacterial infection might not result in pus cells in the urine, except intermittently. Blood agglutination is hardly enough in this case to exclude *brucella* infection. Intradermal skin tests should be done with a mixed *Brucella* antigen, which, together with the results of the blood cultures, should give conclusive evidence as to the presence of undulant fever. Nothing is said about the blood pressure. If it tends to run low, it would be advisable to examine the blood salt and to determine the blood sugar tolerance. Certainly an exhaustive and authoritative examination of at least six daily stool specimens should be made with reference to protozoa. Malaria cannot be fully excluded until blood smears have been taken twice daily by both thick and thin methods for at least five days. If all procedures as suggested are negative, it would be well to use a tuberculin reaction as a means at least of excluding a low grade tuberculous process.

#### PERIURETHRAL ABSCESS IN GONORRHEA

*To the Editor:*—A white man, aged 29, contracted gonorrhea Jan. 19, 1936. It has been confined to the anterior urethra and there is no prostatic or testicular involvement. About four weeks after infection he developed a periurethral abscess about 1½ inches from the glans, on the under surface, which was opened and drained. It gradually healed and three weeks later flared up again. It was reopened and then again gradually healed over after a period of about two weeks. There have been no more flare-ups, but since that time he has never been free from a urethral discharge. It varies, at times completely stopping, but at other times there is as much discharge as there was at the onset. The abscess has gradually decreased in size until now it is about the size of a small pea and is hard, indurated and nonfluctuant. For the past six weeks I have been massaging it twice weekly over a sound and then instilling 10 per cent neosilvol, but the discharge still alternates worse and better, with positive organisms. He has had gonococcus filtrate in gradually increasing doses since the onset. Would it be wise to try and dissect the whole abscess or what is left of it? If so, and the urethra was punctured, would this fistula heal or be permanent? There is no doubt in my mind that he is getting a reinfection from this abscess. Would hyperpyrexia in an electrical cabinet, as reported recently by some authors, effect a cure, in your opinion? If this is published, please omit name. M.D., Alabama.

*ANSWER:*—One of the objections to excision of a periurethral infiltration is the fact that every so often the operation is followed by a fistula and it is because of this possibility that surgery should be used as a last resort. It might be advisable to soak the part in a pitcher of hot water twice a day for fifteen minutes. After the hot soaks, the small nodule or nodules should be massaged.

The passage of sounds and massage of the nodules on the sounds should be continued. If gonococci are found, it might be well to change from neosilvol to strong protein silver or mild protein silver. Hyperpyrexia is rather heroic treatment for this condition.

If the program, as outlined—soaking the part in hot water followed by massage, massage of the infiltration on sounds in the urethra with injections of silver salts—do not render the discharge free from gonococci, it might be well to examine the urethra with a urethroscope and through the urethroscope fulgurate the infected follicle.

#### CHRONIC ULCERATIVE COLITIS

*To the Editor:*—A white youth, aged 18 years, a college student, over a year ago following an acute pharyngitis developed a severe diarrhea consisting of from eight to twelve movements each day. With bismuth therapy evacuations became normal. Two months later, when he was suffering from an emotional experience, the diarrhea returned. Since then there have been persistent symptoms of colitis: diarrhea, loss of weight, pallor, irritability, and occasional streaks of blood in stools. There have been periods lasting several weeks without any diarrhea, and with weight increase. Diet, drugs and mixed vaccines have been used without permanent results. Kindly suggest further therapeutic and diagnostic procedures. Please omit name. M.D., New York.

*ANSWER:*—The story strongly suggests the presence of chronic ulcerative colitis, which commonly appears following an intercurrent infection. It tends to flare up with such infections and it is often made worse by an emotional upset. The diagnosis can be made positively by sigmoidoscopic examination, which will probably show either actual ulceration or else swelling and reddening and fragility of the mucous membrane. X-ray examination may show also that the distal end of the colon is beginning to be scarred and narrowed, with haustration lost.

The disease is a chronic one which, unless checked, will lead to the death of the patient. It is helpful to look on it much as one has to look on pulmonary tuberculosis; unless the patient and his physician will face the situation promptly and seriously as they do now in cases of tuberculosis, and unless the treatment is long continued, involving rest in bed and mental peace, the disease will continue to advance. The time for strenuous treatment is at the beginning before the colon is converted into scar tissue.

J. A. Barga reports cures or arrests with his methods in about 70 per cent of the cases. These methods will be found described in "Management of Ulcerative Colitis," New York, National Medical Book Company, in "The Colon, Rectum and Anus," by Drs. Rankin, Barga and Buie, Philadelphia, W. B. Saunders Company, in the third volume of Oxford Medicine and in many articles. His treatment consists largely of rest in bed, a low residue diet, and what he believes is a specific vaccine and serum.

Two points need emphasis: One, that since the disease is a chronic one that may take months or years to cure, any diet used must be sufficient to maintain good health; it must contain all substances necessary for nutrition. Many patients with

standardize serums and biologic products. The unification of health statistics, the publication of health information and the interchange of health officers between different countries have all proved further fruitful fields of activity. The Health Organization has cooperated extensively with other League of Nations groups and international organizations. This has been especially noteworthy with regard to the league commissions on opium traffic, mandates, transit and economics and with the Red Cross, the International Labor Office and the Pan-American Sanitary Bureau. Not the least of its contributions has been its aid in supplying technical cooperation with the health administrations of various countries. Thus, for example, China, Greece and Bolivia all made requests for cooperation in the reorganization of their health services in the same year. The Health Organization of the League carries on a number of miscellaneous activities through commissions and subcommissions, including the Committee of Health Experts on Infant Welfare, the Cancer Commission, Expert Commission on Plague and the International Sleeping Sickness Commission. To the large majority of American physicians who are unaware of the widespread activity of the Health Organization of the League of Nations, this discussion by Heiser is a revealing document.

## Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

### ALABAMA

**Lecture on Medical Ethics.**—Dr. Thomas Herbert Patton, Tuscaloosa, lectured, March 5, on medical ethics and economics at the University of Alabama School of Medicine. The lecture was the first in a recently established annual lectureship on this subject. Following the lecture, copies of the "Principles of Medical Ethics," published by the American Medical Association, were presented to the students.

### CALIFORNIA

**County Hobby Show.**—The Alameda County Medical Association will hold its first annual hobby show at the California College of Arts and Crafts, Oakland, March 27-29. Dr. Paul Michael is chairman of the hobby committee.

**Library Memorial Fund.**—The Los Angeles County Medical Association has created a library memorial fund in commemoration of deceased members. In the future, instead of sending flowers on the death of a member, the association will contribute to a fund which will be used to increase the educational facilities of the library. Friends of the deceased member may also give to the fund. According to the bulletin of the society, the fund was established at the death of Dr. David G. Ghrist, February 2, with donations from his friends.

**Society News.**—A symposium on splenic disease was presented before the San Francisco County Medical Society, February 9, by Drs. Stacy R. Mettier, Salvatore P. Lucia, H. Brodie Stephens, Robert S. Stone and Zera E. Bolin. —The Alameda County Medical Association was addressed, March 15, by Drs. William H. Strietmann on "Medical Aspects of Renal Disease"; Emil B. Leland, "Earlier Diagnosis of Upper Urinary Tract Lesions"; Albert M. Meads, "The Acute Symptoms of Chronic Hydronephrosis," and Paul P. E. Michael, "Laboratory Procedure in Kidney Disease." —Dr. Douglas R. Drury, Los Angeles, addressed the Hollywood Academy of Medicine, March 18, on "Recent Advances in Physiology and Their Application to Clinical Medicine." —Dr. Joseph B. DeLee, Chicago, addressed the San Diego County Medical Society, February 9, on "Fetal Birth Injuries."

### CONNECTICUT

**Changes in Health Officers.**—The *Connecticut Health Bulletin* announces the following changes in health officers:

Dr. Howard G. Stevens, of New Milford to succeed Dr. Frederick E. King, resigned, and of Bridgewater to succeed the late Dr. Mary G. Haskins.

Dr. John D. Donohue, health officer of the town of Montville to succeed the late Dr. Morton E. Fox.

Dr. Joseph Magnano, health officer of Middlesex County to fill the unexpired term of Dr. Jacob E. Waldman.

**Commission to Study Mental Patients.**—A special commission has been appointed by the governor for a scientific study of mental defectives in Connecticut, to work in cooperation with the Carnegie Institution of Washington. The study, financed by the institution, will be based on the population and waiting list of the Mansfield State Training School and Hospital and will cover types of cases of mental defectives, number, family backgrounds and treatment.

### ILLINOIS

**Dinner to Honor Dr. Black.**—Dr. Carl E. Black Sr. will be guest of honor at a dinner, April 29, when the Morgan County Medical Society will present a special program commemorating his fifty years in the practice of medicine in Jacksonville. The speakers will include Drs. Rolland L. Green, Peoria; Fred W. Bailey, St. Louis; William Allen Pusey, Arthur D. Black, Loyal Davis and Kellogg Speed, Chicago; Clifford U. Collins, Peoria, and Edmund B. Montgomery, Quincy. Dr. Black graduated from Northwestern University Medical School in 1887. He is 75 years of age. He was president of the Illinois State Medical Society in 1904, of the Morgan County Medical Society in 1927 and of the Western Surgical Association in 1930.

### Chicago

**Goodwill Industries' Report.**—During 1936 the Goodwill Industries employed 192 handicapped persons, who received \$53,203 in wages. Sixty-four handicapped persons were enrolled in courses on lip reading, weaving, tailoring, sewing, hat cleaning, household appliances, furniture repair, hand crafts. Because of lack of funds it was necessary to close the curative work department, and as a result only fifteen persons were served in this phase of the program. According to a report, the Goodwill Industries is 85 per cent self supporting through the sale of finished products.

**Dr. Ranson to Lecture.**—Dr. Stephen W. Ranson, professor of neurology and director of the Neurological Institute, Northwestern University Medical School, will deliver the first annual Alpha Omega Alpha Lecture April 2 in the Medical and Dental Laboratories Building of the University of Illinois College of Medicine. His subject will be "The Functional Significance of the Hypothalamus." The lectureship has been established to commemorate the thirty-fifth anniversary of the founding of Alpha Omega Alpha and will be given annually in the future. The medical fraternity, with chapters in fifty-six class A medical schools, was founded at the University of Illinois College of Medicine in 1902.

**Compilation of Data on Maternal Deaths Completed.**—The Maternal Welfare Committee of the Chicago Gynecological Society has completed its self-assigned work of securing case reports on maternal deaths in Chicago but announces that the report will not be available for some time. For 1936 a record of every maternal death in the hospital and the home was obtained. Personal interviews are being made to obtain the few that are missing for 1934 and 1935. The forms adopted by the committee, to be filled out by the hospital, were considered so satisfactory that the city board of health put them into use January 1 for recording similar information, making the report mandatory. The study was instituted in 1934 with a view to considering controllable factors in maternal mortality; it was financed by the Chicago Gynecological Society. Dr. Fred L. Adair is chairman of the maternal welfare committee, which will not be disbanded but will serve in an advisory capacity to the board of health on questions involving policy in the maternal welfare work in Chicago.

### INDIANA

**University News.**—A bronze medallion portrait of the late Dr. Edward Francis Hodges, the work of the late Ikko Matsumoto, was recently presented to the Indiana University Medical Center, Indianapolis, by Mrs. Matsumoto, Indianapolis. Dr. Hodges died in 1916; he had been a member of the faculty of Indiana Dental College, now the Indiana University School of Dentistry, and for more than twenty-five years was on the faculty of the Indiana University School of Medicine.

this disease go down hill because their diet is too restricted. Another point that is often forgotten is that since the disease is an infectious one, involving all the coats of the colon and commonly the lymphatics in the mesentery, the use of medicated enemas is illogical; they cannot possibly reach the disease and, what is more, they commonly make the patient worse.

#### PNEUMOCOCCIC MENINGITIS OR BRAIN ABSCESS

*To the Editor:*—I have a patient in the hospital who was diagnosed as having a pneumococcal meningitis and who presented the following history: A white, married woman, about 35 years of age, was seized with a chill and fever one week ago. She went to bed immediately and soon became irrational, complaining of a headache, and had vomited once during the night and also the following morning. The temperature ranged from 100 to 103 F. She was hospitalized the following day and remained in a somnolent state but could be aroused. The deep reflexes were exaggerated for the first three days, later becoming somewhat decreased. Spinal puncture was done on the fourth, fifth and sixth days. On the fourth day there was no increase in pressure, sugar was decreased, there was increased globulin, the fluid was slightly turbid, the cell count was 191, chiefly polymorphonuclears, and occasional pneumococci were found. On the fifth day there was no increase in pressure, slight turbidity was noted, globulin was increased, the cell count was 141 polymorphonuclears, and there was decreased sugar. On the sixth day there was a slight increase in pressure, the fluid was clear, the cell count in the first test tube was 110, in the second test tube 39, and no pneumococci were found. I would appreciate an outline of treatment and also the prognosis. Anti-pneumococcus serum is being used with general supportive treatment. Please omit name.

M.D., Indiana.

**ANSWER.**—From the evidence submitted, it is difficult to make a diagnosis of a pneumococcal leptomeningitis. This type of disease usually results in the most abundant amount of turbid fluid and excessive polynucleosis (predominance of polymorphonuclear leukocytes) of all the acute purulent leptomeningitides. The number of polymorphonuclear leukocytes is in the thousands. The treatment, however, should be that of any acute meningitis: spinal drainage every twelve hours until the fluid is clear and no cells are found; 100 cc. daily of 50 per cent dextrose solution intravenously for relief of the increased intracranial pressure; replacement of fluid either by copious amounts of water by mouth or from 1,000 to 2,000 cc. of physiologic solution of sodium chloride and 5 per cent dextrose solution intramuscularly every day if needed. Antipneumococcus serum should be given intravenously if it is positively determined that the organism observed is a gram-positive diplococcus; if the organism is a gram-negative diplococcus, antimeningococcus serum should be given intravenously. Supportive treatment should be directed to the cardiorenal, respiratory and gastrointestinal systems. The prognosis cannot be given with the evidence supplied. A true pneumococcal leptomeningitis is invariably fatal, while a meningismus or epidemic cerebrospinal meningitis offers a more favorable outcome. It is suggested that this patient be observed for a possible cerebral abscess. If the latter is found, neurosurgical intervention will be necessary.

#### CHRONIC PAIN AT SECOND METATARSAL HEAD

*To the Editor:*—For the past fifteen years a patient of mine has had trouble with her feet, the head of the second metatarsal of each foot being much depressed, the right more so than the left. There is no pain in any other part of the foot, and the patient is not relieved by arch supports. The patient stoops in an effort to lessen the pain of this area while walking. Also her activities are much curtailed because of pain due to pressure of the bone. What might one expect for the patient's future activities if the metatarsal head is removed? Any information concerning this condition will be appreciated. Please omit name.

M.D., Massachusetts.

**ANSWER.**—Pain in the region of the second metatarsal head is usually due to excessive pressure on this area followed by pathologic changes such as callus formation, bursitis, tenosynovitis, arthritis (traumatic) or periostitis. All these changes may be present in varying degrees at the same time. Excessive pressure beneath the head of the second metatarsal bone is produced by a variety of conditions, such as excessive length of the metatarsal as compared to that of the first and third metatarsal bones, abnormal depression of the metatarsal head secondary to hammer toe deformity, the increased vertical thrusts found in cavus (hollow foot) deformity, and restricted dorsiflexion at the ankle. The use of flexible shank shoes may contribute to this picture of increased pressure. Infraction of the metatarsal head (Freiberg's disease), which is an aseptic necrosis of the head, may be present.

The bilateral character of this symptom associated with poor general posture points toward a long standing static defect rather than primary bone disease. Roentgenograms of both feet should be made. Treatment is directed toward the distribution of weight over as large an area as possible, thus lessen-

ing the weight per unit of area. Felt pads of generous size may be strapped to the foot or glued to the inner sole of the shoe, just behind the metatarsal area. Metatarsal bars, curved or straight, made of leather and about three-sixteenths inch thick may be fastened to the outer surface of the posterior portion of the sole. The shoe should be of sufficient length, with rigid shank and medium height heel. The stockings must be of a length that will not restrict toe motion. Active and passive stretching of the toes into a position of flexion as well as calf stretching exercises are indicated. Excision of the metatarsal head is seldom indicated and, if done, may fail to give relief unless the basic maldistribution of weight is corrected.

#### CARBOHYDRATE INTAKE IN DIABETES

*To the Editor:*—1. A man, aged 48, diabetic, 10 pounds (4.5 Kg.) underweight, shows a trace (less than 0.1 per cent) of dextrose in the urine when he takes 50 Gm. of carbohydrate at each of three meals. When he reduces the carbohydrate intake at meals to 40 Gm. and adds 25 Gm. of carbohydrate three times a day (bread and milk) between meals and before retiring, he shows no glycosuria. He is not taking insulin and needs the additional carbohydrate. Shall he continue to take his carbohydrate in this manner? 2. In a diabetic patient with a high carbohydrate tolerance, is it wise to give carbohydrate to the limit of his capacity, giving less of proteins and fats, especially the latter? 3. A patient with diabetes shows traces (less than 0.1 per cent) of dextrose in the urine after taking certain fruits (cantaloup, honeydew melon, bananas) even though the amount he takes is within his carbohydrate tolerance when he takes other foods. Can this be explained by supposing that carbohydrates of certain foods are absorbed more quickly than others? Please omit name.

M.D., New York.

**ANSWER.**—1. Unquestionably the luncheons of 25 Gm. of carbohydrate should be given between meals and before retiring; but one should not expect that the results will always be the same when the glycosuria is so slight. Very likely the patient might tolerate 40 Gm. of carbohydrate at breakfast, 50 Gm. at noon and 60 Gm. at the late evening meal, and in addition small quantities of food at other times.

2. Theoretically a bridge might sustain 10 tons, but would one strengthen it by loading it to the limit? Carbohydrate does stimulate insulin production but even the advocates of the high carbohydrate diet do not favor the administration of carbohydrate when the blood sugar is rising.

3. It is quite possible that carbohydrate in one form may be absorbed more quickly than in another. Thus, with protamine zinc insulin one likes to give a slowly absorbable carbohydrate in preference to a quickly absorbable carbohydrate which is appropriate in the treatment of reactions due to regular insulin.

One should be sure that the sugar in the urine is dextrose and not levulose or pentose. An investigation of this point might solve the whole situation.

#### EPHEDRINE SALTS INTERNALLY

*To the Editor:*—What are the objections, when clinical relief is obtained, to large doses of ephedrine internally; e. g., 15 grains (1 Gm.) daily in divided doses, for several days, in the severe exacerbations of asthma? I have tried this in many asthmatic patients and found no elevation of blood pressure. What are the incompatibilities of ephedrine internally, particularly when given with iodides, tincture of hyoscyamus and solution of potassium arsenite? Please omit name.

M.D., New York.

**ANSWER.**—There would be no objection to giving 1 Gm. daily in divided doses, provided the untoward manifestations, such as insomnia and palpitation, are looked out for and antagonized by appropriate means, such as the simultaneous administration of phenobarbital, should they arise. The observation that this dose does not produce definite elevation of blood pressure is in line with the opinion generally held. Ephedrine is not incompatible with any of the medicaments mentioned.

#### URTICARIA AND ABSCESS

*To the Editor:*—I am considering reporting a case of lung abscess the initial symptom of which was generalized urticaria (hives). This symptom at the onset of the illness before the coughing up of any purulent material seems quite unusual to me, and I am writing to inquire whether this is a rare symptom before the drainage of the abscess cavity starts. How often has a case like this been reported in the literature and where?

THOMAS V. Z. GUDEX, M.D., Louisville, Ky.

**ANSWER.**—It is well known that infections anywhere in the body may cause urticaria. No specific cases of urticaria associated with lung abscess are found in a search of the literature. However, this would not be an unusual association. Urticaria accompanying a parasitic abscess would probably be more common than in a bacterial abscess.

**Course in Public Speaking at Medical School.**—Establishment of a course in public speaking at Indiana University School of Medicine, Indianapolis, has been recommended by a committee appointed by the dean, Dr. Willis D. Gatch, to study the subject. It was further suggested that a committee be appointed to confer with a committee from the faculty at Bloomington to explore ways and means to arrange such a course harmoniously, according to the state medical journal. The primary purpose of the course, which would include training in the use of both the written and the spoken word, would be to produce physicians able to write and speak properly before assemblies of physicians or laymen. The committee is composed of Drs. Maurice Joseph Barry, chairman, Thurman B. Rice and Edgar F. Kiser.

### KANSAS

**Dr. Jackson Will Give Porter Lectures.**—Dr. Chevalier Jackson, professor of bronchology and esophagology, Temple University School of Medicine, Philadelphia, will present the Porter Lectureship in Medicine at the University of Kansas School of Medicine, Lawrence and Kansas City. Following is the schedule:

March 30, Kansas City, Cancer of the Larynx.

March 31, Lawrence, The Larynx and Its Care.

March 31, Kansas City, Bronchoscopy in the Diagnosis and Treatment of Disease.

**Personal.**—Dr. Leo V. Turgeon, Wilson, has been appointed a member of the state board of administration for a four year term, and Dr. James M. Scott, Topeka, has been reappointed to a temporary term. State hospitals, the state sanatorium for tuberculosis at Norton and similar institutions are under the jurisdiction of the board.—Dr. James E. Henshall, Osborne, was recently appointed to a four year term on the Kansas State Board of Medical Registration and Examination; Dr. Henry E. Haskins, Kingman, has been reappointed to a four year term.—Dr. Clinton C. Fuller, Columbus, has been appointed health officer of Cherokee County.

### MARYLAND

**Dr. Gamble to Give the Thayer Lectures.**—Dr. James L. Gamble, professor of pediatrics, Harvard University Medical School, Boston, will deliver the William Sydney Thayer and Susan Read Thayer Lectureship in Clinical Medicine at Johns Hopkins University School of Medicine, March 30-31. His subjects will be "Extracellular Fluid in Health and Disease" and "Renal Defense of Extracellular Fluid."

**Annual Banquet of Health Department.**—The Baltimore City Health Department held its thirty-fourth annual banquet, February 2, with Dr. Adolph Weinzirl, then director of the bureau of communicable diseases, as toastmaster. Dr. Weinzirl is now health officer of Portland, Ore. The speakers included Mayor Howard W. Jackson; Dr. Thomas S. Cullen, a member of the state board of health; Dr. John L. Rice, commissioner of health of New York City; Dr. William H. F. Warthen, assistant commissioner of health of Baltimore, and Dr. Huntington Williams, health commissioner.

**Medical-Dental Service Bureau Discontinued.**—The Medical and Chirurgical Faculty of Maryland recently discontinued the Medical-Dental Service Bureau, which began operation April 1. The board of directors of the bureau felt that the medical and dental professions had not displayed sufficient interest to justify its continuance. According to the faculty's bulletin, the fact that only about 10 per cent of the physicians and a little larger percentage of the dentists availed themselves of the services was most discouraging. The board arranged for the liquidation of outstanding debts and retained the charter of incorporation so that operation might be resumed if there is a sufficient demand at any time in the future.

### MASSACHUSETTS

**Medical Adviser to Industrial Board.**—Dr. Matthew V. Norton, Jamaica Plain, has been appointed medical adviser of the Industrial Accident Board of Massachusetts, succeeding the late Dr. Francis D. Donoghue, it is reported. Dr. Norton graduated from Tufts College Medical School in 1929.

**Hospital Bequests.**—Massachusetts General Hospital, Boston, is to receive \$100,000 to establish free beds in the women's department, under the will of William A. Sargent of Brookline. A similar bequest will go to the New England Deaconess Hospital. Both gifts will be memorials to Mr. Sargent's mother, Martha Sargent.

**New Marine Hospital.**—A site has been selected in Boston for a new U. S. Marine Hospital, replacing the antiquated one at Chelsea, built about 1860. According to the *Health*

*Officer* the plans call for a 350 bed hospital on a tract of land covering about 579,000 square feet, which is in Commonwealth Heights, Brighton, overlooking the Charles River Basin and Boston Harbor. The title of the site was held in the name of the Massachusetts Memorial Hospital, whose trustees purchased it in 1929.

### MICHIGAN

**Glee Club and Orchestra Hold Joint Concert.**—The doctors' symphony orchestra and the glee club of the Wayne County Medical Society are rehearsing for a concert to be given jointly, April 26. Georges Miquelle is director of the orchestra and Marcus Kellerman of the glee club.

**New Health Directors.**—Dr. Clifton E. Merritt, Coldwater, has been appointed in charge of the newly established health department in Dickinson County, and Dr. Lloyd H. Gaston, Gladwin, formerly director of health district number 7, has been chosen to direct the new department in Sanilac County. Dr. Edwin Vanderslice, Lansing, has been placed in charge of health district number 7, comprising Clare, Gladwin and Arenac counties.

### MISSOURI

**New Hospital for Negroes Dedicated.**—The new \$3,160,000 Homer G. Phillips Hospital for Negroes, St. Louis, was dedicated and opened for patients February 22. Replacing city hospital number 2, the building formerly used by the old Barnes Medical College, the new hospital occupies all but one corner of two city blocks and consists of an administrative building with two ward wings to care for 600 patients, a service building and a nurses' and superintendent's home. The speakers at the dedicatory exercises included Governor Starck, Mayor Dickmann, Secretary of the Interior Harold L. Ickes; Father Alphonse M. Schwitalla; Dr. Earle Williams, Lovejoy, Ill., president of the Mound City Medical Association; Dr. Midian O. Bousfield, Chicago, of the Rosenwald Fund; Dr. Roscoe C. Giles, Chicago, president of the National Medical Association, and Dr. Numa P. G. Adams, dean, Howard University School of Medicine, Washington, D. C. Dr. Orval S. McClellan is superintendent of the institution. PWA grants supplied \$625,000 of the building cost.

### NEW YORK

**Prize for Reports on Pneumonia.**—The advisory committee of the New York State Department of Health will award a prize of \$100 to the physician in New York outside New York City who submits the best report of a series of cases of pneumonia. If the writer desires, the report may be documented by clinical histories and laboratory reports; but the report itself should not be longer than 5,000 words and should be in a form suitable for publication in the *New York State Journal of Medicine*. Reports should be in the hands of the committee not later than August 15 and the award will be made October 1.

### New York City

**Dr. Healy to Give Salmon Lectures.**—Dr. William Healy, director of the Judge Baker Guidance Center, Boston, will deliver the fifth series of Thomas William Salmon Memorial Lectures at the New York Academy of Medicine Friday evenings, April 9, 16 and 23. Dr. Healy's subjects will be "Foundations of the Personality Structure," "The Developing and Emerging Personality" and "Personality in Widening Human Relationships." Dr. Healy has been director of the Judge Baker Foundation since 1917. Previously he was director of the psychopathic institute of the juvenile court of Chicago. He was graduated from Rush Medical College, Chicago, in 1900.

**Dr. Russell Retires.**—Dr. William L. Russell, general psychiatric director of the Society of the New York Hospital since 1926, retired January 1 and was appointed consulting psychiatrist of the hospital and medical director emeritus of the Westchester Division (formerly Bloomingdale Hospital), White Plains. Dr. Russell, a native of Canada, was graduated from University Medical College, New York University, in 1885. After several years of private practice in New York he was appointed assistant physician at the Willard State Hospital, serving from 1897 to 1903, when he became medical inspector for the New York State Hospital Commission. In 1910 he was appointed medical superintendent of the Long Island State Hospital and in 1911 went to Bloomingdale Hospital as medical director, remaining until his appointment as general psychiatric director in 1926. Dr. Russell is professor of psychiatry emeritus at Cornell University Medical College. He is 73 years old.

## Medical Examinations and Licensure

### COMING EXAMINATIONS

#### STATE AND TERRITORIAL BOARDS

Examinations of state and territorial boards were published in *THE JOURNAL*, March 20, page 998.

#### NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS: *Parts I and II*. May 10-12, June 21-23, and Sept. 13-15. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

#### SPECIAL BOARDS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Written examination for Group B applicants* will be held in various cities throughout the country on April 17. *Oral examinations for Group A and B applicants* will be held in Philadelphia, June 7-8. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF INTERNAL MEDICINE: *Practical examination* will be given in St. Louis, April 23, and at Philadelphia in June. Chairman, Dr. Walter L. Biering, 406 Sixth Ave., Rm. 1210, Des Moines.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: *Practical, oral and clinical examinations for Group A and B applicants* will be held at Atlantic City, N. J., June 7-8. *Applications must be received at least sixty days prior to the examination dates*. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY: Philadelphia, June 7 and Chicago, Oct. 9. *All applications and case reports, in duplicate, must be filed at least sixty days before the date of examination*. Sec., Dr. John Green, 3720 Washington Blvd., St. Louis, Mo.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY: Atlantic City, N. J., June 8. *Applications must be sent to the Secretary prior to April 1*. Sec., Dr. Fremont A. Chandler, 6 N. Michigan Ave., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY: Philadelphia, June 7-8. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

AMERICAN BOARD OF PEDIATRICS: Atlantic City, N. J., June 6. Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Illinois.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY: Philadelphia, June 2. *To be considered for this meeting, applications must be in the hands of the Secretary before April 2*. Sec., Dr. Walter Freeman, 1028 Connecticut Ave., Washington, D. C.

AMERICAN BOARD OF RADIOLOGY: Atlantic City, N. J., June 4-6. Sec., Dr. Byrl R. Kirklin, Mayo Clinic, Rochester, Minn.

AMERICAN BOARD OF UROLOGY: *Written examinations* will be held in various cities in the United States, April 3. *Oral examination*, Minneapolis, June 25-26. Sec., Dr. Gilbert J. Thomas, 1009 Nicollet Ave., Minneapolis.

### Connecticut November Examinations

Dr. Thomas P. Murdock, secretary, Connecticut Medical Examining Board, reports the written examination held at Hartford, Nov. 10-11, 1936. The examination covered 9 subjects and included 70 questions. An average of 75 per cent was required to pass. Thirty-six candidates were examined, 28 of whom passed and 8 failed. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
George Washington University School of Medicine.....	(1935)	75.9*	75.
Georgetown University School of Medicine.....	(1935)	75.2	
Rush Medical College.....	(1933) 75, (1934)	76.1*	
University of Maryland School of Medicine and College of Physicians and Surgeons.....	(1936)	80.9*	
Boston University School of Medicine.....	(1935)	77.8*	
Harvard University Medical School.....	(1929) 83.3, (1935)	84.8	
Tufts College Medical School.....	(1933)	82.7,	
(1934) 75, (1935) 75, 75.3, (1936) 83.3*			
University of Michigan Medical School.....	(1934)	78.2	
St. Louis University School of Medicine.....	(1936)	79.1	
Columbia Univ. College of Physicians and Surgeons.....	(1935)	76.7	
Long Island College of.....	(1936)	75.3*	
New York University.....	(1936)	80.6	
University of Rochester.....	(1934)	80.1,	
(1935) 77.6*			
University of Oregon Medical School.....	(1932)	89.9	
University of Pennsylvania School of Medicine.....	(1933)	75, 83.2	
University of Vermont College of Medicine.....	(1935)	76.7	
Queen's University Faculty of Medicine.....	(1929)	75.9	
McGill University Faculty of Medicine.....	(1934)	84.8	
School	FAILED	Year Grad.	Per Cent
University of Illinois College of Medicine.....	(1936)	73.3	
St. Louis University School of Medicine.....	(1935)	72	
Long Island College of Medicine.....	(1935)	71.9	
Laval University Faculty of Medicine.....	(1933)	66.8	
Regia Università degli Studi di Roma. Facoltà de Medicina e Chirurgia.....	(1935)	73.6†	
Osteopaths, 3†			

Twenty-six physicians were successful in the oral examination for endorsement applicants given in Hartford, November 24. The following schools were represented:

School	PASSED	Year Grad.	Endorsement of
Yale University School of Medicine.....	(1934)* (1934), (1935) N. B. M. Ex.		
Emory University School of Medicine.....	(1933)		Georgia
Johns Hopkins University School of Medicine.....	(1933)*		Maryland
Harvard University Medical School.....	(1933)*		
(1927)* Massachusetts, (1924), (1930, 2),* (1932), (1934) N. B. M. Ex.			
Tufts College Medical School.....	(1934) N. B. M. Ex.		
University of Michigan Medical School.....	(1929)* Michigan		

Columbia Univ. College of Physicians and Surgeons... (1933) New York, (1934)\* N. B. M. Ex.

Queen's University Faculty of Medicine..... (1926) Minnesota  
\* License has not been issued.  
† Verification of graduation in process.  
‡ Examined in medicine and surgery. Average grade not reported.

## Book Notices

**Allergic Diseases: Their Diagnosis and Treatment.** By Ray M. Balyeat, M.A., M.D., F.A.C.P., Associate Professor of Medicine, University of Oklahoma Medical School, Oklahoma City. Assisted by Ralph Bowen, B.A., M.D., F.A.A.P., Chief of Pediatric Section, Balyeat Hay Fever and Asthma Clinic, Oklahoma City, Oklahoma. Fourth edition. Cloth. Price, \$6. Pp. 516, with 132 illustrations. Philadelphia: F. A. Davis Company, 1936.

This edition is similar in many ways to the three previous ones. There is considerable new material; the chapter on the allergic phases of dermatology has been given a great deal of space and is well written; the differential diagnosis between contact dermatitis and allergic eczema is likewise well done. The use of iodized oil in the treatment of chronic bronchial asthma is fully discussed and the technic is easily understandable. However, other investigators have not obtained such brilliant results by its use as has the author of this book. The photographs and tables deserve much commendation; the language is lacking in medical phraseology and seems to be written for the public and medical students rather than for the trained physician. The book is to be strongly criticized because of its lack of editing and the amount of repetition. For example, the subject of heredity is dealt with over and over again and the relationship of rabbit hair to mattresses is repeated with almost identical words in several parts of the book. The size of the book could be materially reduced by careful attention to such details. The percentage of positive skin tests in cases of migraine and urticaria seems too high. Most other workers find few such patients with positive skin tests. The author is also to be criticized for applying the term "sensitive" to an antigen when he implies that the patient has given a positive skin test. The word "sensitive" should mean "clinically sensitive" and not skin test positive. The writer also uses the term "perennial hay fever" for cases of rhinitis due to animal dander, orris root and dust. It would seem best to restrict the term "hay fever" to patients hypersensitive to pollen and only to pollen. The perennial allergic type could be included under the term "allergic" or "hypersensitive rhinitis."

**Le développement psychique de l'enfant et de l'adolescent. Évolution normale.—Pathologie.—Traitement.** Manuel d'étude. Par Edouard Pichon, médecin des hôpitaux de Paris. Paper. Price, 45 francs. Pp. 374. Paris: Masson & Cie, 1936.

This book is written in a concise, clear style and is easy to understand. Although definitely psychoanalytic in his approach, the author displays an excellent knowledge of neuropsychiatry and psychology. The book is divided into five parts. Part one has to do with the methods of child psychology, intelligence testing, observing and questioning of children and case history taking. Part two traces the normal mental development of children, including speech, motor ability, thought processes and emotional development. Part three concerns the disturbances of mental development, including mental deficiency, endocrine dysfunctions, neuropathologic conditions, perversions, psychoses, epilepsies and emotional instability. Part four discusses education from an academic, familial and social point of view. Part five discusses therapy both psychologic and pharmacologic. The author does not attempt to present the entire field of any subject but reviews briefly the important problems of child psychology and develops many valuable ideas and criticisms. Some of the modern psychologists will be disappointed to find that the author in his consideration of intelligence adopts a nativistic point of view and quotes Leibnitz's famous reply to Locke. This view is in striking contrast to the rest of the book. Many educators may take issue with his insistence on the importance of the reality principle in all forms of educa-

**Columbia to Enlarge Laboratory Facilities.**—Columbia University College of Physicians and Surgeons will add eight floors to the west wing of its building at Broadway and One Hundred and Sixty-Eighth Street to enlarge its laboratory facilities for graduate medical education, Dr. Willard C. Rappleye, dean of the college, recently announced. The expansion is made possible by gifts amounting to \$500,000, half of which was a grant from the Commonwealth Fund. There will be laboratories for anatomy, pathology, biologic chemistry, physiology and bacteriology. The new facilities will be a further advance in the program of graduate medical education which Columbia has been developing for several years. A variety of short courses has been organized in the hospitals and clinics associated with the college: some for the general practitioner who wishes to keep abreast of medical knowledge; some for the specialist already practicing, and others for those who need only a short period of training to qualify for certification by one of the national specialty boards. Affiliations with leading hospitals of the metropolitan area make available ample clinical facilities; key men on the staffs of these hospitals have been or will be appointed to the teaching staff of the university. In addition to the short courses, for which university credit is not given, Columbia has offered since 1932 the degree of doctor of medical science to identify those who complete a program of study on a university level in one of the specialized fields of clinical medicine. Only residents appointed in one of the affiliated hospitals may register for this degree. With the new extensions the university can now provide a wide variety of opportunities for every phase of medical education under a flexible plan of study at a university level and with adequate laboratory and clinical facilities to meet every educational need, the dean's announcement states.

### PENNSYLVANIA

**Hospital Appointments.**—The Delaware County Hospital, Upper Darby, has appointed Dr. Thomas A. Shallow, professor of surgery, Jefferson Medical College, Philadelphia, director of the department of surgery to succeed the late Dr. Edward J. Klopp. Dr. Frederick J. Kalteyer, clinical professor of medicine at Jefferson, was appointed director of the medical department, and Dr. Howard S. Busler, Lansdowne, director of the department of otolaryngology.

### Philadelphia

**Potter Lecture.**—The William Potter Memorial Lecture at Jefferson Medical College was delivered, February 11, by Dr. Henry A. Christian, Hersey professor of the theory and practice of physic, Harvard University Medical School, Boston. His subject was "The Fruition of a Clinician."

**Dr. Clerf Appointed to New Position.**—Dr. Louis H. Clerf, formerly professor of bronchoscopy and esophagoscopy at Jefferson Medical College, has been elected professor of laryngology and bronchoscopy. In addition to his present duties, Dr. Clerf will assume the duties formerly discharged by Dr. Fielding O. Lewis, who has been made emeritus professor of laryngology and consulting laryngologist to Jefferson Hospital.

**Radio Talks on Venereal Disease.**—Through its committee on venereal and cutaneous diseases, the Philadelphia County Medical Society is presenting a series of radio talks on venereal disease. The titles used are as follows:

- Why the Public Should Know About Syphilis and Gonorrhea.
- The United States Public Health Service and Syphilis.
- How Does Syphilis Spread?
- What Is Syphilis?
- Syphilis in the Expectant Mother and Her Offspring.
- What Price Syphilis (Community and Industry)?
- The Need for Intelligent Treatment of Syphilis.
- Syphilis Is Curable.
- What Is Gonorrhea?
- Gonorrhea Is Curable.

**John Scott Medals Awarded.**—The city of Philadelphia through its board of city trusts conferred the John Scott Awards for 1937 at a ceremony March 5 on Dr. Everts Ambrose Graham, Bixby professor of surgery, Washington University School of Medicine, St. Louis; William D. Coolidge, Ph.D., director of the research laboratory of the General Electric Company, Schenectady, N. Y., and Irving Langmuir, Ph.D., associate director of the same laboratory. Dr. Graham was honored for his application of x-rays to the study and diagnosis of diseases of the gallbladder; Dr. Coolidge for his development of the modern x-ray tube, and Dr. Langmuir for his invention of the tungsten filament incandescent electric bulb. The awards are \$1,000, a copper medal and a certificate. The Scott awards were given to Philadelphia by a Scotch chemist in 1816 to reward persons whose work "adds to the comfort, welfare and happiness of mankind." The original gift was \$4,000, but in the 120 years of its existence the fund has grown

to more than \$100,000. Why John Scott chose Philadelphia to administer it has never been known, the Philadelphia *Inquirer* says: he never came to the city and was not known there except for a possible acquaintance with Benjamin Franklin.

### WASHINGTON

**Obstetric Society Organized.**—A group of physicians interested in obstetrics met in Tacoma January 30 to form the Washington State Obstetrical Society. Dr. Henry H. Skinner, Yakima, was elected president; Dr. Robert N. Hamblen, Spokane, vice president, and Dr. Philip C. Kyle, Tacoma, secretary. Meetings are to be held the first Saturdays of April and October.

**Personal.**—Dr. Frank W. Maier, Wilbur, has been appointed house physician at the State Custodial School at Medical Lake. —Dr. William A. Mitchell, Colfax, has been appointed health officer of Whitman County to succeed Dr. Robert J. Skaife. —Dr. Sanford P. Lehman, formerly of Wooster, Ohio, has been appointed health officer of Olympia and of Thurston County to succeed Dr. Beverly D. Holland, who has been appointed to the Army Medical Corps.

**Surgical Meetings.**—Dr. Curle Latimer Callander, associate clinical professor of surgery and topographical anatomy at the University of California School of Medicine, San Francisco, was the guest speaker at the annual meeting of the Spokane Surgical Society, February 20. Dr. Callander made three addresses: "Gastro-Intestinal Embryological Principles as Applied to (a) Splenectomy, (b) Resection of Major Portion of the Duodenum and Head of the Pancreas for Carcinoma, and (c) Sliding Hernia of the Cecum and Sigmoid," "New Amputation Through the Femur at the Knee" and "New Methods of Diagnosis and Treatment of Gas Bacillus Infection." —The annual clinics of the Seattle Surgical Society were held January 22-23 at King County Hospital Unit No. 1 (Harborview), with Dr. Harry M. Richter, professor of surgery, Northwestern University Medical School, Chicago, as the guest speaker. —Dr. John M. T. Finney Jr., associate in surgery, Johns Hopkins University School of Medicine, Baltimore, was the guest speaker at the annual meeting of the Puget Sound Surgical Society in Seattle, March 13. Dr. Finney conducted clinics during the day at King County Hospital and addressed a banquet meeting in the evening at the Rainier Club on "Pyloroplasty and Duodenostomy."

### GENERAL

**Orthopedic Examination.**—The American Board of Orthopaedic Surgery will hold its next examination in Atlantic City June 8. Applications must be sent before April 1 to the secretary, Dr. Fremont A. Chandler, 6 North Michigan Avenue, Chicago.

**Golf Tournament at Atlantic City.**—The American Medical Golfing Association will hold its annual tournament at Seaview Country Club in Atlantic City Monday June 7. The directory of the association is being revised and members are asked to send their correct addresses to the secretary, William J. Burns, 2020 Olds Tower, Lansing, Mich.

**Cooperation by Commissioner of Narcotics with State Licensing Agencies.**—Information as to the narcotic addiction of any applicant for a license or permit of any kind, or of any licensee or permittee, and as to the conviction of the violation of any law relating to narcotic drugs by any such applicant, licensee or permittee, may now be furnished by the United States Commissioner of Narcotics to any state licensing agency, whenever such addiction or conviction may have a material bearing on the granting, withholding, suspension or revocation of a license or permit. Prior to the promulgation of Treasury Decision 25, March 2, 1937, such information could be disclosed only with respect to licenses relating to professions and trades in the course of which narcotic drugs are possessed, controlled or dispensed.

**Radiology Societies Employ Field Secretary.**—Mr. Mac Cahal, since 1931 executive secretary of the Sedgwick County Medical Society, Wichita, Kan., has been employed as field secretary to represent the American Roentgen Ray Society, the Radiological Society of North America, the American Radium Society and the American College of Radiology. Mr. Cahal was selected by an interlocking committee recently appointed to represent the four societies. Members of the committee are Drs. Arthur C. Christie, Washington, D. C., chairman; Edward H. Skinner, Kansas City, and Lowell S. Goin, Los Angeles. Beginning April 1 Mr. Cahal will maintain headquarters in Chicago at 2561 North Clark Street but will travel throughout the country. He will be concerned primarily with improving

tion. Others may feel that he is a bit too moralistic. However, it is one of the few books that deal with some of the practical aspects of the handling of atypical children. It is directed to the general physician to whom children are brought needing psychiatric care and whose duty it becomes to counsel the parents of these children. For this purpose it is excellent and is recommended to those engaged in child guidance work.

**Treatment in General Practice: The Management of Some Major Medical Disorders. Volume II.** Articles republished from the *British Medical Journal*. Cloth. Price, 10s. 6d. Pp. 426, with illustrations. London: H. K. Lewis & Co., Ltd., 1936.

To those who have profited by volume I of this series, which included a discussion of diseases of the respiratory tract, acute specific fevers and cardiovascular diseases, this volume will be welcome. It deals with diseases of the nervous system, of the digestive system and of the blood and blood forming organs, rheumatic diseases, metabolic diseases and diseases of the kidney. As with the previous volume, this is a reprint of articles that appeared in the *British Medical Journal* during the past year. As the articles were written on invitation by eminent clinical teachers, each of them might be considered to represent the voice of British authority on the subject. If a certain degree of conservatism is manifest, characterized by a tendency to keep alive certain therapeutic measures that might well be permitted to lapse into oblivion, this must be credited to the habitual attitude of our British confrères.

**Diseases of Infancy and Childhood.** By Wilfrid Sheldon, M.D., F.R.C.P., Physician for Diseases of Children, King's College Hospital, London. With a foreword by G. F. Still, M.A., M.D., LL.D. Cloth. Price, \$7. Pp. 738, with 137 illustrations. Philadelphia: P. Blakiston's Son & Co., Inc., 1936.

There seem to be so many books dealing with the diseases of children that this one must be examined regarding its justification. It is neither a handbook nor a large reference work. According to the author it represents the clinical teaching and lectures on pediatrics given in the children's department and postgraduate courses at King's College Hospital. As stated by Dr. G. F. Still in the foreword, "It carries not merely the stock-in-trade of every medical textbook but the fruit of personal experience; so that opinions expressed have been checked by clinical observation, and as such are of solid worth." He further states "It is the function of such a book as this to keep us abreast of recent developments and particularly of the latest methods available for helping children in their time of sickness." The book is unusually well illustrated for one of its size, which alone should commend it. Occasional bibliographic references are given at the bottom of the pages, most of them being from the British literature. Conditions such as tuberculosis of the bones and joints, osteomyelitis and cleft palate have been intentionally omitted because of their surgical nature, although they belong in a pediatric textbook as much as does intussusception. The book is thoroughly down to date, as evidenced by the mention of mandelic acid in the treatment of urinary infections and convalescent serum in poliomyelitis. The book is a well composed, well illustrated, fairly complete, concise pediatric textbook written in the English manner and from an English pediatrician's point of view.

**Anatomy of the Human Body.** By Henry Gray, F.R.S., Fellow of the Royal College of Surgeons, Lecturer on Anatomy at St. George's Hospital Medical School, London. Twenty-third edition thoroughly revised and re-edited by Warren H. Lewis, B.S., M.D., Professor of Physiological Anatomy, Johns Hopkins University, Baltimore. Cloth. Price, \$10. Pp. 1,381, with 1,216 illustrations. Philadelphia: Lea & Febiger, 1936.

Twenty-three editions of Gray's Anatomy, a medical classic, have appeared since the publication of the first English edition in 1858. The volume has had several editors but throughout the course of its development has maintained a constant approach to this fundamental medical book. In the present edition the various sections have been brought down to date by the incorporation of new additions to anatomic knowledge, particularly in the sections on embryology and on the ductless glands, where research has centered in the last few years. In the revision of the text of the section on the central nervous system, Dr. David McK. Rioch of Harvard University Medical School has carried the responsibility. Some new illustrations have been added and older ones replaced. The Basle anatomical nomenclature in English is followed. The current volume is prefaced by a portrait and a brief biography of Henry Gray, author of the first edition.

**Lane Medical Lectures: Studies in Cardiovascular Regulation.** By G. V. Anrep, M.D., D.Sc., F.R.S., Professor of Physiology, Medical Faculty, Egyptian University, Cairo. Stanford University Publications, University Series. Medical Sciences, Volume III, Number 3. Paper. Price, \$1.50. Pp. 118, with 38 illustrations. Stanford University, California: Stanford University Press; London: Oxford University Press, 1936.

In this series of five lectures, Professor Anrep takes a well deserved place among a group of brilliant and distinguished men who have delivered the Lane medical lectures since 1896. His contribution provides additional distinction for the series. The subject is discussed under the topics proprioceptive mechanism of cardiovascular regulation, respiratory regulation of the heart rate, dynamics of the coronary circulation, coronary blood flow and blood flow through the skeletal and plain muscles. The work is almost entirely that of Professor Anrep and his colleagues, although there is liberal reference to similar work in other laboratories. The tasks have been carried out with meticulous care and attention to detail. No statement is made that is not proved to the satisfaction of the author; and the author is a severe critic. To the clinician he offers much material for careful thought and not a little opportunity for clinical investigation. The clinical picture of shock and asphyxia is at once adorned with new significance after one has read the lecture on the proprioceptive mechanism. The coronary circulation is dealt with from a wholly physiologic standpoint but the clinical implications cannot be missed. The work on human heart-lung preparations is especially interesting and subsequent reports will be awaited with interest. In the preface the author states that he has succeeded in answering only a few questions but that he hopes he has been able to raise many more. He has succeeded in answering enough questions to make it profitable for all who are interested to read the answers and he has succeeded in raising enough questions to provide much opportunity for research, both clinical and physiologic.

**Food and the Principles of Dietetics.** By Robert Hutchison, M.D., LL.D., F.R.C.P., Consulting Physician to the London Hospital, and V. H. Mottram, M.A., Professor of Physiology at King's College of Household and Social Science, University of London. Eighth edition. Cloth. Price, \$6.75. Pp. 634, with 3 illustrations. Baltimore: William Wood & Company, 1936.

In some respects a review of such a work as this might be likened to gilding the lily. The chronological progress of the editions dates from 1900, when the textbook was first published. It appears as though a lot of the material contained in the original edition is still retained, thirty-six years later. This should be of greater interest to the bibliophile than to the practitioner, as it presents clearly in both quotation and paraphrase a summary of the properly endorsed bibliographic references of nutrition in the nineties. A close perusal of the total material reveals few, but some, misconceptions with reference to modern views concerning food. As the book devotes only about 140 pages to the large field of infant and adult feeding in disease, as a textbook for immediate institution of diet therapy it may be considered somewhat inadequate. The volume is heartily recommended as a source of physiologic food principles as well as a mine of information relative to the reactions to food of the body when in a pathologic state.

**Seventy Years of It: An Autobiography.** By Edward Alsworth Ross, Ph.D., LL.D., Professor of Sociology, University of Wisconsin. Cloth. Price, \$3. Pp. 341, with 9 illustrations. New York & London: D. Appleton-Century Company, Incorporated, 1936.

Edward A. Ross, for many years professor of sociology in the University of Wisconsin, records here the story of his life, a career noted for its independence, its effect on the world and his contribution to American scholarship. He writes in a personal reflective manner and he supplements his book with innumerable quotations from magazines, newspapers, personal correspondence and other sources, which he has selected with fine editorial judgment. One of the most interesting and humorous chapters is a section of some twelve pages of quotations from his personal correspondence without any other note than a single headline for each. Like many another university professor, Ross was subject during his career to investigation by a state legislature, and his account of these investigations has at present a highly journalistic interest. The book will well repay lovers of autobiography.

the relations of all radiologists with organized medicine. The appointment is for three years and will be financed by the four societies.

**Council Formed to Coordinate Cancer Activities.**—At the request of the National Association of Science Writers, the American Society for the Control of Cancer has sponsored the formation of a council to act as a clearing house for information and to integrate and coordinate the activities of the major cancer organizations in the United States. The following were appointed members of the council: Drs. Frank E. Adair, New York, and the late Robert B. Greenough, Boston, to represent the American College of Surgeons; Karl Kornblum, Philadelphia, the American Roentgen Ray Society; James B. Murphy, New York, and Clarence C. Little, Sc.D., Bar Harbor, Maine, the American Association for Cancer Research; Drs. James Ewing, New York, and Burton T. Simpson, Buffalo, the American Society for the Control of Cancer. It is believed that unwise or premature publicity may be forestalled or its effects minimized by the council's work, claims of successful treatments or cures may receive prompt and authentic criticism, and abuse of public confidence may be prevented.

**Bequests and Donations.**—The following bequests and donations have recently been announced:

Children's Hospital of Philadelphia and Babies' Hospital of Philadelphia, \$5,000 each by the will of William E. Sellers.

The following hospitals receive \$5,000 each by the will of the late Samuel Church, Hahnemann Medical Protestant Episcopal Methodist, Presbyterian, St. Temple University, Women's Southern Children's hospitals and St. Christopher's

American Oncol \$5,000 from the estate of Miss Mary Edmunds, in recognition of cancer research work done by Dr. George M. Dorrance.

Episcopal Hospital, Philadelphia, \$2,000 from the estate of Charlotte C. McCreight.

Northeastern Hospital, Philadelphia, \$1,000 by the will of William Wiseman.

Hahnemann Hospital, Philadelphia, about \$3,000 to establish three beds in memory of her parents, by Mrs. Kate Van Alen.

Frederick Douglas Memorial Hospital, Philadelphia, \$1,000 by the will of Clifford Phillips.

Brooklyn Hospital, Brooklyn, N. Y., \$10,000 by the will of the late William Gilman Lowe.

Hunt Memorial Hospital, Danvers, Mass., \$100,000 by the will of the late Williams C. Endicott.

Presbyterian Hospital, Philadelphia, \$5,000 by the will of George Miller. Memorial Hospital for the Treatment of Cancer and Allied Diseases, New York, \$20,000 from Mrs. Irma Straus in memory of her husband, the late Jesse Isidor Straus, ambassador to France.

## Government Services

### Examination for Appointment to Public Health Service

The U. S. Public Health Service announces an examination for eligibility to appointment in the regular corps of the service in the grade of assistant surgeon (medical only). Examiners will be in the following places to make physical examinations and to conduct the oral and general fitness portion of the examination:

- U. S. Veterans' Facility, Atlanta, Ga., April 12.
- U. S. Marine Hospital, New Orleans, April 13.
- U. S. Veterans' Facility, Kansas City, Mo., April 16.
- Psychopathic Hospital, Denver, April 17.
- U. S. Marine Hospital, San Francisco, April 19.
- U. S. Marine Hospital, Seattle, April 22.
- U. S. Veterans' Facility, Minneapolis, April 26.
- U. S. Marine Hospital, Chicago, April 27.
- U. S. Marine Hospital, Cleveland, April 28.
- U. S. Public Health Service Hospital, Lexington, Ky., April 29.
- U. S. Public Health Service Building, Washington, D. C., May 3.

Applicants who pass these preliminary examinations may participate in the written examination May 3, either at the place where the physical examination is conducted or at some nearer point; or they may come to Washington to take the entire examination May 3. The oral and physical fitness portion of the examination will consume one or two days, while the written and clinical portions will consume not less than five days. Travel expenses are to be paid by the candidates. Applicants must not have passed their thirty-second birthday, must be citizens of the United States, must be graduates of class A medical colleges and must have completed at least one year of internship or its equivalent since graduation. The compensation of officers in the grade of assistant surgeon is \$3,158 per annum with dependents and \$2,699 without dependents. If time will permit, application blanks may be obtained from the surgeon general, Washington, D. C.; otherwise they may be obtained from the board of examiners at the time of examination. Applicants will be required to present their diplomas to the board.

### A Dietary Survey

The Medical Research Council has published a survey of the food eaten by representative communities in England and Scotland, which is the third of three reports by Prof. E. P. Cathcart and Mrs. A. M. T. Murray. A point brought out in the earlier investigations was the relative constancy in the distribution of calories between protein, fat and carbohydrate eaten by people in different towns. In particular the constancy of the percentage of protein eaten was remarkable: 11.03 in St. Andrews, 10.16 in Cardiff and 10.32 in Reading. Yet the foods eaten in these towns differed widely. Throughout the past fifty years, discussions of food and nutrition have largely centered round the calory value of the diet, and 3,000 calories a day per man for many became a standard. More recently the figure has been raised to 3,400 calories. But according to Professor Cathcart and Mrs. Murray the daily diet of 109 women students averaging 21 years of age contained 2,035 calories. The physique and health of these women was good and the question arises whether misplaced trust has not been put in the standard of 3,000 calories. The technical commission set up by the Health Committee of the League of Nations gave an allowance of 2,400 calories a day as adequate for an adult male or female living an everyday life in a temperate climate and not engaged in manual work. The observations of Cathcart and Murray are in closer agreement with this figure than with the much quoted 3,000 calories. Their main conclusion is that few of the diets examined in these various towns, when considered from the point of view of energy, protein, fat, percentage of first class protein and mineral salts, can be regarded as poor. But many of them leave much to be desired in their content of "protective" foodstuffs, such as milk, green vegetables and fruit. The authors therefore stress the need of educating the housewife in the relative value of different foodstuffs. Ignorance and stupidity, even when there is abundant money for food, often prevent the best nutrition from being obtained. Valuable results could be obtained, even among families with small incomes, by educational means. The main causal factor of inadequate diets in many households is ignorance of how to buy, what to buy and how to use to the best advantage the material bought. There was often an excessive expenditure at the beginning of the week on tasty foodstuffs that gave a poor return for money spent and a period of bare maintenance later. Balance of expenditure was an art ignored by many and, despite narrow means, the waste on days of plenty was often high. Lack of means of course plays a part in defective diets, but the authors hold that, though improved economic conditions may play a part in the amelioration of diets, the greater good will be attained by educational means.

### Committee of Medical Association and the Trades Union Congress

An important new departure has taken place by the agreement of the council of the British Medical Association and the general council of the Trades Union Congress to set up a joint committee on medical questions. The terms of reference will be as wide as possible, each side being free to bring forward for the consideration of the committee (which will be purely advisory) any question on which it desires advice. The questions likely to be considered are such general ones as the provision of a general medical service, contractual arrangements between physicians and workmen, and the developments of industrial medicine. The joint committee will also provide, either directly or through a subcommittee, arbitration machinery

### MEDICOLEGAL ABSTRACTS

#### Workmen's Compensation Acts: Medical Services Supplied by Incorporated Clinic Formed by Employers.

—The medical aid law of Washington permits certain employers, with the consent of a majority of their employees, to enter into contracts with "physicians, surgeons and owners of hospitals operating the same, or with hospital associations" for medical, surgical and hospital care for injured workmen. Eight employers formed a corporation, the Lumbermen's Clinic, to provide this care for employees of the incorporators of the clinic. Medical aid contracts were entered into between the clinic and corporations with which one or more of the incorporators of the clinic were interested. The clinic also entered into so-called "nonincidental" contracts with employees, providing for care during sickness and injury not received in the course of extra hazardous employment. These "nonincidental contracts" were paid for by the workmen at the rate of 25 cents a day for the first four days of the month during which they were employed. An information in the nature of quo warranto was filed by the state against the clinic, charging, among other things, that it was not a hospital association and could not therefore make contracts to supply medical services to injured workmen, that it was unlawfully engaged in the practice of medicine, and that it was carrying on the business of insurance without having obtained a license so to do. The trial court held that the clinic was not a hospital association within the meaning of the medical aid statute and that its medical aid contracts were illegal. The clinic was restrained from making further contracts until it had reorganized in such a manner as to bring itself within the provisions of the medical aid law. A period of ninety-days was allowed within which the clinic could take such action. Both the clinic and the state appealed to the Supreme Court of Washington.

The Supreme Court did not pass on whether the clinic had violated the medical practice act or the insurance laws of the state. But, in the opinion of the court, the clinic was operating beyond the scope of the statute under which it was formed, and exercising franchises or privileges not conferred by law. The clinic was organized, according to the preamble to the articles of incorporation, "in conformity with the laws of the state of Washington relative to corporations and associations formed for religious, social and for charitable purposes." The court could find no trace of any religious, social or charitable activities carried on by the clinic. On the contrary, the incorporators were motivated by the idea that they or the corporations in which they were interested would receive some advantage from the operation of the clinic. Profit does not necessarily mean a direct return by way of dividends, interest, capital accounts or salaries. The saving of expense which would otherwise necessarily be incurred is also a profit to the person benefited. If the clinic rendered to its incorporators or members, or to businesses in which they were interested and in whose profits they shared, a service at a cost lower than that which would otherwise be paid for such service, then the clinic's operations result in a profit to its members. The employers were obligated, under the law, to pay for medical aid for which the state made a certain charge. The setting up by a group of employers of this clinic to furnish medical aid at a less cost than that charged by the state certainly resulted in a profit to the members of the clinic. Furthermore, the trial court was clearly correct, said the Supreme Court, in holding that the clinic was not such a hospital association as met the requirements of the medical aid statute. The judgment of the trial court, subject to certain modifications, was affirmed.

In separate opinions two justices expressed the view that the clinic was clearly conducting a health and accident insurance business without having complied with the insurance code. Furthermore, the obvious purpose of the provisions of the medical aid statute under consideration, in the opinion of one of these justices, was to relieve the employer and workmen from contributing to the state medical aid fund. It was equally

clear that the provisions relating to contracts contemplated that such contracts should be made with operators of hospitals—persons or corporations engaged in the business of hospitalization and treatment of patients brought in for their medical and surgical care. The clinic operated no such hospital. It was a perversion of the statute, in the opinion of this justice, to permit a group of employers to band together for the sole purpose of "farming out" their injured employees to such surgeons and hospitals as they might choose.—*State ex rel. Troy v. Lumbermen's Clinic (Wash.)*, 58 P. (2d) 812.

## Society Proceedings

### COMING MEETINGS

- Alabama, Medical Association of the State of, Birmingham, April 20-22. Dr. D. L. Cannon, 519 Dexter Ave., Montgomery, Secretary.
- American Association for the Study of Neoplastic Diseases, Philadelphia, April 9-10. Dr. E. R. Whitmore, 2139 Wyoming Ave. N.W., Washington, D. C., Secretary.
- American Association on Mental Deficiency, Atlantic City, N. J., May 5-8. Dr. E. Arthur Whitney, Elwyn, Pa., Secretary.
- American College of Physicians, St. Louis, April 19-23. Mr. E. R. Loveland, 4200 Pine St., Philadelphia, Executive Secretary.
- American Pediatric Society, University, Va., April 29-May 1. Dr. Hugh McCulloch, 325 North Euclid Ave., St. Louis, Secretary.
- American Physiological Society, Memphis, Tenn., April 21-24. Dr. A. C. Ivy, 303 East Chicago Ave., Chicago, Secretary.
- American Psychiatric Association, Pittsburgh, May 10-14. Dr. William C. Sandy, State Education Bldg., Harrisburg, Pa., Secretary.
- American Society for Clinical Investigation, Atlantic City, N. J., May 3. Dr. J. M. Hayman Jr., 2065 Adelbert Road, Cleveland, Secretary.
- American Society for Experimental Pathology, Memphis, Tenn., April 21-24. Dr. Shields Warren, 195 Pilgrim Road, Boston, Secretary.
- American Society for Pharmacology and Experimental Therapeutics, Memphis, Tenn., April 21-24. Dr. E. M. K. Geiling, 947 East 58th St., Chicago, Secretary.
- American Society of Biological Chemistry, Memphis, Tenn., April 21-24. Dr. H. A. Mattill, Chemistry Building, State University of Iowa, Iowa City, Secretary.
- Arizona State Medical Association, Yuma, April 1-3. Dr. D. F. Harbridge, 15 East Monroe St., Phoenix, Secretary.
- Arkansas Medical Society, Little Rock, April 12-14. Dr. W. R. Brooksher, 602 Garrison Ave., Ft. Smith, Secretary.
- Association of American Physicians, Atlantic City, N. J., May 4-5. Dr. Hugh J. Morgan, Vanderbilt University Hospital, Nashville, Tenn., Secretary.
- California Medical Association, Del Monte, May 2-5. Dr. F. C. Warnshuis, 450 Sutter St., San Francisco, Secretary.
- Connecticut State Medical Society, Bridgeport, May 19-20. Dr. Creighton Barker, 258 Church St., New Haven, Secretary.
- District of Columbia, Medical Society of the, Washington, May 5-6. Dr. C. B. Conklin, 1718 M St. N.W., Washington, Secretary.
- Federation of American Societies for Experimental Biology, Memphis, Tenn., April 21-24. Dr. Shields Warren, 195 Pilgrim Road, Boston, Secretary.
- Florida Medical Association, St. Petersburg, April 5-7. Dr. Shaler Richardson, 111 West Adams St., Jacksonville, Secretary.
- Georgia, Medical Association of, Macon, May 11-14. Dr. Edgar D. Shanks, 478 Peachtree St. N.E., Atlanta, Secretary.
- Hawaii Territorial Medical Association, Hilo, April 30-May 2. Dr. Douglas B. Belf, Queen's Hospital, Honolulu, Secretary.
- Illinois State Medical Society, Peoria, May 18-20. Dr. Harold M. Camp, 202 Lahl Bldg., Monmouth, Secretary.
- Iowa State Medical Society, Sioux City, May 12-14. Dr. Robert L. Parker, 3510 Sixth Avenue, Des Moines, Secretary.
- Kansas Medical Society, Topeka, May 3-6. Mr. Clarence G. Munns, Stormont Bldg., Topeka, Executive Secretary.
- Louisiana State Medical Society, Monroe, April 26-28. Dr. P. T. Talbot, 1430 Tulane Ave., New Orleans, Secretary.
- Maryland, Medical and Chirurgical Faculty of, Baltimore, April 27-28. Dr. Walter Dent Wise, 1211 Cathedral St., Baltimore, Secretary.
- Minnesota State Medical Association, St. Paul, May 3-5. Dr. E. A. Meyerding, 11 West Summit Ave., St. Paul, Secretary.
- Mississippi State Medical Association, Meridian, May 11-13. Dr. T. M. Dye, McWilliams Bldg., Clarksdale, Secretary.
- Missouri State Medical Association, Cape Girardeau, May 10-12. Dr. E. J. Goodwin, 634 North Grand Blvd., St. Louis, Secretary.
- Nebraska State Medical Association, Omaha, May 11-13. Dr. R. B. Adams, 15 N Street, Lincoln, Secretary.
- New Hampshire Medical Society, Manchester, May 18-19. Dr. Carleton R. Metcalf, 5 South State St., Concord, Secretary.
- New Jersey, Medical Society of, Atlantic City, April 27-29. Dr. J. B. Morrison, 66 Milford Ave., Newark, Secretary.
- North Carolina, Medical Society of the State of, Winston-Salem, May 3-5. Dr. L. B. McBrayer, Southern Pines, Secretary.
- North Dakota State Medical Association, Grand Forks, May 16-18. Dr. Albert W. Skelsey, 20½ North Broadway, Fargo, Secretary.
- Ohio State Medical Association, Dayton, April 28-29. Mr. C. S. Nelson, 79 East State St., Columbus, Executive Secretary.
- Oklahoma State Medical Association, Tulsa, May 10-12. Dr. L. S. Willour, 203 Ainsworth Bldg., McAlester, Secretary.
- South Carolina Medical Association, Columbia, April 13-15. Dr. E. A. Hines, Seneca, Secretary.
- Tennessee State Medical Association, Knoxville, April 13-15. Dr. H. H. Shoulders, 706 Church St., Nashville, Secretary.
- Texas, State Medical Association of, Fort Worth, May 10-13. Dr. Holman Taylor, 1404 West El Paso St., Fort Worth, Secretary.
- Western Branch of American Public Health Association, Phoenix, Ariz., April 13-15. Dr. William P. Shepard, 600 Stockton St., San Francisco, Secretary.

in industrial disputes. It will consist of seven representatives from each side. It is claimed that interchange of views between the medical profession and trade unionists can result only in mutual good in the public interest.

### Better Factory Conditions

In a previous letter the factories bill was described. A campaign has been instituted to improve it by a committee which admits that in the main the provisions for the health, safety and welfare of the workers are good but says that those concerning hours of work and overtime are disappointing. They suggest the following amendments: Washing facilities should be provided in all factories, not only in those of dirty or offensive trades. Accommodation for outdoor clothing should be available in all factories and not only by regulation in dirty, dusty and offensive trades. Other demands are seats for all workers whose work is done standing and a statement that their use, when the opportunities for resting occur, shall not be restricted; hours of work for young persons to be limited to forty instead of to forty-eight per week and their work not to start before 7 a. m. or continue after 6 p. m.; no overtime to be allowed for young persons; the period of employment for women to be between 7 a. m. and 8 p. m., instead of between 6 a. m. and 9 p. m.; certificates of fitness to be required for all young persons, not merely up to the age of 16. The committee also asks that the age of entry into factories should be 15, or the school-leaving age, whichever is the higher; that an hour be allowed for the midday meal; that a mess room be provided with the means of heating food, where more than twenty persons are employed, and that the provision of the Washington Convention, giving six weeks' cessation of work before and after childbirth with benefit for maintenance of mother and child, be ratified in the bill.

### Precautions Against Gas Attacks

Precautions for the defense of the country against air attacks are being rapidly made on a large scale. Those against gas attacks are particularly of medical interest. Masks of three main types are being made. The first is the standard army service type and can be worn for forty-eight hours without adjustment. This will enable men engaged in decontamination work, casualty evacuation or the control of any of the essential services in areas where the concentration is heavy and the hours of service long and continuous to carry on with perfect confidence. The construction of the mask is simple and it is guaranteed effective against any of the poison gases at present known to the government, excepting such vesicants as liquid mustard and lewisite, for which special protective clothing must be worn. The gas masks for the civilian population are of a different type and are designed to cause less resistance to breathing. For this and other reasons they can be worn without discomfort by elderly persons and by children over the age of 4 or 5 years. These masks are of two kinds, one good for from six to eight hours, the other for three or four hours. The former mask, called the service type, is intended for those on special duties, such as stretcher bearing, point duty and shifts in factories and public works. The latter type, called the standard civilian mask, which is being produced in large quantities, gives sufficient protection for the civilian to take cover in a gas-proof shelter or to escape altogether from the danger zone. Students are being trained in the use of these masks as well as in antigas preparations in general.

#### GAS MASKS FOR BABIES

The government is experimenting with three types of gas mask for small children. One is a portable cradle with a complete cover; the second is a special hood which completely envelops an ordinary perambulator; the third is a box in which a baby can sleep soundly. One or all of these types may be adopted and issued to the public free.

### REFUGEES AGAINST GAS ATTACKS

Simple devices by which people can provide their own safeguards against gas poisoning and injury during air raids have been shown at an exhibition at Kensington town hall. Maps and models explained the plans which the borough council had prepared for the protection of the people in such an emergency. The plan involves the conversion of swimming baths into a large first aid station. There will be four main self-contained depots for decontamination and first aid work. It was shown how a house could be made proof against poison gas. Paper and paste are all that are required for casement windows, with a damp blanket ready to be pulled down like a blind. For sash windows an old carpet or blanket can be placed over the whole surface and secured round the sides by laths and tacks.

### Nurses in Hospitals in 1762

Florence Nightingale is generally credited with the introduction of nurses into military hospitals (during the Crimean War), but in a lecture delivered at the Royal College of Surgeons on "John Hunter in the Campaign in Portugal" Prof. G. E. Gask cited earlier examples. In 1762 Hunter went to Portugal to serve on the only military hospital at Lisbon. Female nurses were included in this expeditionary force and were attached to the staff of the hospital. The matron was Mrs. Sullivan and there were two head nurses and three cooks. But female nurses were employed even earlier—in the wars in Ireland in the time of William and Mary and in "the Seven Years War" in Germany. But there was no evidence of the training of these women. However, Professor Gask thought that the appointment of a matron and two head nurses in control suggested that they were specially picked, perhaps from nurses in the civil hospitals.

### Social Insurance Guide for Physicians in France

In France, syndicates or unions composed of almost all the licensed physicians in each department (county) take charge of the public relations of the profession. The Syndicate of the Department of the Seine is the largest in France. In one of its monthly bulletins the details of the contract made with the social insurance authorities by the syndicate are given. The following principles, which should guide the members of the syndicate in their daily dealings with the insured, are of interest as showing the amount of "paper" work and "red tape" which the execution of such a law requires:

1. The general principle of the law is that every physician takes care of an insured individual as if that person were a patient in his ordinary practice.
2. Every worker whose annual salary does not exceed 18,000 francs (about \$900 since devaluation) is obliged to be insured. If the worker has one dependent child less than 16 years old, the limit is raised to 20,000 francs; if there are two dependent children the limit becomes 22,000 francs, and if there are three dependents it becomes 25,000 francs. The beneficiaries are the insured (male or female), the husband or wife of the insured and dependent children less than 16 years old.
3. The insured has the right to select his or her physician for all services rendered either at the domicile of the assured or in the office of the physician but not at public hospitals. The caisses or disbursing agency of the social insurance organization cannot exclude any physician from treating the insured because he is not a member of the syndicate. The underlying principle which guides the caisses is that the insured should be treated by the local practitioner; hence no allowance is granted for mileage or similar expenses in case a physician is called who does not practice in the given community.
4. The insured is obliged to ask the caisses for a special blank on which the attending physician writes the person's name and

**Collapse Therapy in Pulmonary Tuberculosis.**—Leslie and Anderson give the final results of an intensive collapse therapy program for 1,124 patients of a single large sanatorium, including 823 discharged and 301 resident patients. Collapse therapy in some form was instituted in 72.3 per cent of the discharged patients. It was recommended in 81 per cent of the entire series and was actually used in 78.8 per cent. Of 823 discharged patients, arrest or apparent arrest of the tuberculosis was secured in 47.3 per cent, favorable results in 67.1 per cent, cavity closure in 57 per cent of cavity cases, closure or decrease in the size of cavities in 69.6 per cent, sputum conversion in 59 per cent of the positive cases and negative sputum in 70.7 per cent of the discharged patients, of whom only 28.6 per cent had negative sputum throughout the entire period of treatment. Of 595 discharged patients who received collapse therapy, the figures for similar results were invariably much higher, being respectively 55.4, 77.8, 71.3, 84.2, 72.7 and 79.3 per cent. Corresponding figures for cavity and sputum results for the entire series of patients were usually slightly higher than the foregoing figures for the discharged group alone. A comparison of these results with those of a large number of sanatoriums using relatively little collapse therapy as an average clearly shows that the former are vastly superior from every point of view. The results presented constitute an overwhelming argument in favor of a definite policy of early and intensive collapse therapy for approximately three fourths of the patients with the adult type of tuberculosis in the civilian sanatoriums of this country.

**Iodine-Resistant Hyperthyroidism.**—In his study of thirty-nine patients who had hyperthyroidism and who were iodine resistant, Blanck observed that the noteworthy characteristic was the relatively short duration of symptoms. It appears that the previous ingestion of iodine is not instrumental in effecting the iodine-resistant state. In attempting to correlate this relatively short duration of symptoms, a more logical interpretation may be found in the contention of Means, who believes that the iodine-resistant state may be explained on the basis that the medication is given at a time when the disease

is rapidly increasing in severity and that the effect of the iodine is merely to hold the status constant. Following the relatively short duration of symptoms, the next principal feature is the preoperative period of iodization. Closely associated with changes in metabolism are the changes in the pulse, weight and clinical picture. There was an average rise in metabolism of 4.4 per cent. Taken alone this would suggest an intensification of the existing thyrotoxicosis. However, notwithstanding this average rise in metabolism there was an associated depression of 3.7 beats per minute in the average pulse rate and an average weight gain of 2½ pounds (1.1 Kg.). Further, 81 per cent of these patients experienced definite clinical improvement. Although these changes are not as striking as those noted in the cases making an average response to preoperative medication, they suggest that, despite the rise in metabolism, these patients are in a measure definitely improved by preoperative iodization. The immediate response of these patients to surgical intervention (one-stage operation of Richter) is reflected in the relatively mild postoperative course and in the fact that there did not occur a single operative fatality in this series. The results, however, are in only partial agreement with other discussions on the iodine-resistant thyroid. To clarify this apparent discrepancy the author reviewed, for additional evidence, the last 1,500 consecutive thyroidectomies for primary, secondary and recurrent hyperthyroidism in the services of Richter. There were nine fatalities, in each of which there was wanting evidence of the iodine-resistant state. In 16 per cent there was a persistent mild hypothyroidism and in 82 per cent there was no hypothyroidism at the end of 23.3 and 27.3 months, respectively. These figures are in accordance with similar observations made in large series of cases having an average response to iodine. In this series the important feature was the uniform presence of persistently hyperplastic areas. Persistent focal areas of hyperplasia distributed throughout the gland may be sufficient to elevate or maintain a constant basal metabolic rate. On the other hand, that some improvement does occur following iodization can be reconciled in that the gland does undergo partial involution, and hence the degree of preternatural activity is reduced but not completely controlled. What appears to be of greater importance is that a complete uniform involution does not always follow iodization. Why focal areas of hyperplasia should persist that have resisted the involution produced by iodine is a matter of conjecture.

**Effect of Temperature on Emptying Time of Stomach.**—The work done by Sleeth and Van Liere on the emptying time of the stomach in five normal dogs shows that low environmental temperature decreases the emptying time of the stomach, while high environmental temperature increases the gastric emptying time. Four animals exposed to temperature averaging 15 F. showed an average decrease of 17 per cent in the emptying time of the stomach, while the same number

## SUMMARY AND CONCLUSIONS

1. Motor accidents are occurring with increasing frequency, so that severe facial injuries necessitating surgical treatment are becoming more numerous.

2. Facial disfigurements are a source of great mental anguish and not infrequently engender psychologic handicaps that ruin social and business careers. The ranks of the unemployed and unemployable are already large enough in these days of keen competition without adding unnecessarily to their numbers persons physically and mentally handicapped by preventable and curable facial defects.

3. Proper attention to details of diagnosis and treatment at the time of first aid treatment is necessary if good results are to be obtained.

4. When infections and other complications prevent proper care soon after the accident, plastic procedures should be deferred to a later date.

5. No surgical treatment should be attempted until it can be done properly. Every effort from start to finish should be directed toward minimizing scar formation and restoring the patient to society with the least deformity in the shortest possible time.

## CHRONIC THYROIDITIS

R. H. JAFFÉ, M.D.  
CHICAGO

In recent years attention has been called to a peculiar disease of the thyroid gland which is characterized by extensive lymphocytic infiltrations, marked reduction of the parenchyma and fibrosis. This disease, which occurs almost exclusively in women, starts insidiously and takes a very chronic course. The clinical manifestations are chiefly due to the pressure of the hardened gland on the trachea, and in the majority of the cases no symptoms of a disturbed thyroid function are encountered. The basal metabolic rate is often within normal range. In a few instances it is increased or diminished. After radical operation myxedema has been observed in about 40 per cent of the reported cases. Since the lymphocytic infiltrations frequently cause an enlargement of the gland, the disease has been classified among the goiters and the misleading adjective "lymphomatous" has been used. Hashimoto has been credited as being the first author to describe this type of goiter, and the term Hashimoto's goiter is often found in the literature (Graham and McCullagh,<sup>1</sup> Clute, Eckerson and Warren,<sup>2</sup> Lee<sup>3</sup> and Emerson<sup>4</sup>). The etiology and pathogenesis of Hashimoto's goiter are still matters of much discussion and there is also considerable controversy as to the relations between Hashimoto's goiter and Riedel's goiter. Many investi-

gators (Boyden, Coller and Bugher,<sup>5</sup> Ewing,<sup>6</sup> Heineke,<sup>7</sup> Heyd,<sup>8</sup> Perman and Wahlgren,<sup>9</sup> Reist,<sup>10</sup> Shaw and Smith<sup>11</sup> and others) see no reason for separating the two types of goiter, and indeed the histologic pictures of the two are so similar that in a given case it may be difficult to decide whether one is dealing with Riedel's type or Hashimoto's type. The differences that are found are quantitative rather than qualitative in nature. Clinically and macroscopically there are sufficient dissimilarities to warrant, at least for the present time, the differentiation of the two types (Graham and McCullagh<sup>1</sup> and Lee<sup>3</sup>), although the two are unquestionably closely related to each other. Wegelin<sup>12</sup> includes both under the general term chronic thyroiditis.

It has been repeatedly regretted that the knowledge of Hashimoto's goiter is based mainly on the material removed at operation and that studies of autopsic material are wanting. It has also been stated that nothing is known about the changes into which the lymphocytic infiltrations of the thyroid gland may terminate. I have observed at the autopsy table lesions of the thyroid which in every respect are identical with those given as characteristic of Hashimoto's goiter, except that the gland is not enlarged but is either of normal size or is smaller than normal. Since, put together, these cases form a continuous line of progressing changes which lead to a well defined pathologic condition that is rarely recognized during life, I have thought it worth while to report briefly on my studies.

EXTENSIVE LYMPHOCYTIC INFILTRATION AND  
FIBROSIS OF THE THYROID GLAND

Four cases belonging to the group in which there was extensive lymphocytic infiltration and fibrosis of the thyroid gland came under my observation and all of these were in women. The thyroid had retained its normal shape, could be easily dissected out and varied in weight between 14 and 25 Gm. The consistency was firm and scarlike, the capsule was thickened and the surfaces made by cutting presented a pale pink gray to a light yellow tan with fine, branched, whitish lines. No structures resembling normal thyroid tissue could be made out with the naked eye. Histologically dense lymphocytic infiltrations and a varying degree of fibrosis were the most striking manifestations. The infiltrations surrounded, invaded and replaced the follicles, the colloid of which had disappeared, while the lining epithelium was desquamated, degenerated and shrunken. In many places the lymphocytes formed nodules with centers that were composed of larger lymphoid cells and swollen reticular cells. Plasma cells were scanty and no giant cells could be found. The wall of the arterioles and small arteries was thickened, and in one of the cases this thickening was very marked. The interlobular and intralobular connective tissue was increased, and in some instances the fibrotic areas predominated over the lymphocytic infiltrations. Three cases showed small islands of fairly intact follicles, which

were enclosed in dense connective tissue, and in these three cases the lesion of the thyroid was merely an incidental finding. One of the patients, a white woman aged 52, had committed suicide by drinking lye. The second patient, a Negress, aged 57, had died of acute yellow atrophy of the liver, and the cause of death of the third patient, a white woman, aged 28, was a verrucous endocarditis complicated by a subacute glomerulonephritis. The fourth case, which disclosed the most extensive changes of the thyroid, is described in detail:

**CASE 1.—History.**—A white woman, aged 58, of American descent, entered the hospital complaining of pain over the left side of the chest and heart, fainting spells, swelling of the hands and eyelids and progressive weakness, which had started six months before. The last menstrual period had occurred at the age of 30.

**Examination.**—On physical examination the patient was moderately obese and listless. The skin was dry, thickened and waxy with a slight degree of scaling. The hair of the head was coarse and dry and the hair of the pubic region was very scanty. The heart and lungs did not show any abnormal changes except that the heart tones sounded distant. The Wassermann reaction of the blood was strongly positive, that

Fig. 1 (case 2).—Gross appearance of the thyroid.

of the spinal fluid negative. The urine did not contain albumin or sugar. The hemoglobin content of the blood was 60 per cent, the erythrocyte count was 4,650,000, and the leukocyte count was 14,000. There were 68 per cent neutrophils, 27 per cent lymphocytes, 3 per cent monocytes and 2 per cent eosinophils. The patient was very uncooperative and a determination of her basal metabolic rate could not be made. The diagnosis was "myxedema" and under thyroid medication the patient improved gradually. After three weeks she started to lose ground rapidly, the temperature rose to 102.6 F. and she died four weeks after admission.

**Autopsy.**—The body weight was 73 Kg. and the body length was 152 cm. The skin was dry and scaly and in the region of the thighs somewhat resembled fish skin. The heart weighed 280 Gm. There was a syphilitic aortitis, which involved the arch, and a marked atheroma of the abdominal aorta and the coronary arteries. There was an arteriosclerotic granulation of the kidneys and an apical scarring of both upper pulmonary lobes. The liver weighed 1,440 Gm., the spleen 125 Gm. and the adrenals 7 Gm. The thyroid weighed 17 Gm. and was firm in consistency and a pale pink gray. The internal genitalia were atrophic. The brain weighed 1,190 Gm. and there was a marked thickening of the leptomeninges, especially about the frontal lobes.

**Microscopic Examination.**—In the leptomeninges there were perivascular infiltrations of lymphocytes, which extended into the cortex. The cortex showed tigrolysis and neuronophagia of the nerve cells and a diffuse proliferation of the microglia

cells. The epidermis was thin and atrophic, while the cutis appeared thickened and contained a pale stained homogeneous material between the connective tissue bundles. The changes of the aorta were typical of syphilitic aortitis. The hypophysis and the pancreas were normal and the lipid content of the cortex of the adrenals was decreased.

The examination of the thyroid showed a most extensive lymphocytic infiltration, with numerous nodules about disintegrating follicles. The epithelial cells of these follicles were swollen and desquamated and in places showed an increased affinity to the eosin stain. In other places the cytoplasm of the epithelial cells was finely vacuolated. The content of these vacuoles did not take the fat stains, but fine fat granules were occasionally present between the vacuoles. There were evidences of attempts at regeneration in the form of a few mitotic figures. There was practically no colloid filled follicle left. A few plasma cells and free histiocytes were scattered between the round cells. The infiltrations were surrounded by much dense connective tissue, which enclosed the residues of shrunken follicles. The wall of the arteries and arterioles was slightly thickened.

#### ADVANCED FIBROSIS OF THE THYROID GLAND

In the two cases of the group in which there was advanced fibrosis of the thyroid gland the thyroid had been replaced by a sclerotic connective tissue. There were sufficient evidences to indicate that this sclerosis was preceded by and had developed from a lymphocytic infiltration of the gland, which was similar to that previously described. Both patients were elderly women and neither one showed the symptoms of myxedema. Of the five cases of sclerosis of the thyroid gland described by Simmonds, only two showed a myxedema. In my two cases a marked anemia was the most outstanding symptom, suggesting a primary disease of the blood-forming organs.

**CASE 2.—History.**—A white woman, aged 55, of German descent, was extremely weak and was not able to give much information. From her daughter it was learned that one week prior to her admission to the Cook County Hospital she had left the State of Wisconsin General Hospital in Madison at her request. Dr. F. J. Pohle, resident physician of this hospital, kindly supplied a detailed account of her stay there, from which the following data are taken: The patient had entered the hospital four weeks prior to her discharge, stating that during the past five months she had noticed a progressing weakness, which became so severe that she was unable to walk without assistance. She had been subject to frequent colds and became dyspneic at the slightest exertion. She was very pale, and about the tibias and ankles a slight edema was found. The blood pressure was 110 systolic, 68 diastolic, and the liver and spleen were palpable. Examination of the blood showed a hemoglobin content of 35 per cent, an erythrocyte count of 1,170,000 and a leukocyte count of 1,250 cells. There were 22 per cent neutrophils, 4 per cent eosinophils, 68 per cent small lymphocytes and 4 per cent metamyelocytes. The platelet count was 60,000. This condition remained constant and, since liver medication had no effect, three blood transfusions were given. The hemoglobin content then rose to 60 per cent and the number of the erythrocytes increased to 3,180,000. The white count, however, remained around 1,200. The clinical diagnosis was subleukemic lymphadenosis. A sore throat developed and the temperature went up to 103 F. The patient insisted on returning to Chicago and was discharged.

At the Cook County Hospital the patient complained of weakness and difficulty in swallowing. Physical examination disclosed a diffuse consolidation of the left lower pulmonary lobe and a very marked anemia. There was a mild stomatitis and a slight cervical lymphadenopathy. The lower border of the liver could be felt but the spleen was not palpable. The temperature varied between 102 and 103.6 F. The hemoglobin content was 29 per cent, the red blood cell count 1,430,000 and the white blood cell count 1,850. The differential count showed 66 per cent monocytes, 7 per cent plasma cells, 14 per cent lymphocytes, 1 per cent irritation forms, 10 per cent segmented neutrophils and 2 per cent staff nucleated neutrophils. There was a moderate anisocytosis with single hyperchromatic and

of animals exposed to temperatures averaging 90 F. showed an average increase of 10 per cent in the emptying time of the stomach. The observation gives experimental evidence for the basis of the recognized fact that an individual often feels more hungry during cold weather and less hungry in extremely warm weather.

**Tuberculous Enterocolitis.**—Fox and his associates declare that abdominal pain, diarrhea, local rigidity and tenderness over the cecum, or a palpable tumor in the same region, are diagnostic of intestinal ulceration in far advanced cases of pulmonary tuberculosis; but these symptoms are not common, or even rare, diarrhea having occurred in only four of their 100 cases. The vague symptoms, such as anorexia, nausea, constipation and varying distress after meals, are more common but in themselves are insufficient for a diagnosis. The degree of intestinal involvement does not always correspond to the amount of pulmonary involvement, and therefore the diagnosis is missed until a later date when tuberculosis in the lungs becomes quite evident. Laboratory help in these cases is insufficient. Roentgen studies hold out the most promising possibilities. The oral method of giving barium sulfate for roentgen observation is the best for studying the ulcerative type of cecal tuberculosis. However, an examination of this region by x-rays is not complete unless barium sulfate is given by mouth and by enema. The terminal ileum was visualized in ninety-seven of the 100 cases at seven hours and in sixty-one cases at nine hours. The percentage with a visualized ileum at nine hours was definitely higher in the pathologic group. Of this group thirty-eight were found to have abnormalities after the oral administration of barium sulfate. Forty-eight with cavitation showed an incidence of 54 per cent of positive roentgen changes, and sixty-eight with positive sputum showed an incidence of 47 per cent of roentgen signs. The incidence of cavitation (68.4 per cent) and positive sputum (84.2 per cent) in the cases with positive roentgenologic changes is markedly higher than the corresponding figures (35.5 and

58 per cent) in those with negative observations. Of the four cases in which there were symptoms, three were roentgenologically positive. The incidence of positive signs was definitely higher by the oral method than by the barium sulfate enema.

**Filament-Nonfilament Count in Tuberculosis.**—Paine and Austin performed nonfilament counts, leukocyte counts and sedimentation rates on seventy-seven tuberculous patients over a considerable period, comparing the three tests as guides to pathologic activity and as warning signals of approaching relapse, with particular emphasis on the nonfilament count. In order to confirm the observations of previous workers, nonfilament counts were done on fifty healthy members of the sanatorium personnel. All were under 16 per cent, ranging from 2 to 16, with an average of 7.7 per cent. Thus the base line of 16 was used as the upper limit of normal. In only nine of the patients studied were the trends of the three determinations in disagreement. For the most part filament-nonfilament and leukocytic counts agreed closely. In the sixteen patients showing steady progression of the lung process all three tests were elevated consistently. In four patients showing a sudden and marked increase of disease neither the filament-nonfilament nor the leukocytic index showed any premonitory rise. Sedimentation rates remained elevated in some patients who were clinically inactive and whose leukocytic index and nonfilament count had returned to normal. The filament-nonfilament count in this study demonstrated no superiority over the leukocytic index.

**Influence of Dried Fruits on Intestinal Flora.**—Weinstein and Weiss find that banana powder, apple powder and raisins, when fed to white rats subsisting on a high protein diet consisting exclusively of raw chopped beef, cause a change in the intestinal flora from one in which nonaciduric bacteria predominate to one in which Bacillus acidophilus is the main organism. Prunes, charcoal and kaolin do not have any visible

acetylsalicylic acid among those hypersensitive to the drug. All the fatal cases of hypersensitiveness to acetylsalicylic acid which we have encountered in the literature have been of this type. Vander Veer,<sup>9</sup> in the course of a discussion of the problem of asthma, stated: "We have the records of at least two dozen aspirin [sensitive] cases, in one of whom there developed an attack of asthma lasting three weeks following the ingestion of 5 grains and another patient who immediately went into shock and died in five minutes." Lamson and Thomas<sup>10</sup> reported the case of a woman with asthma, known to be sensitive to acetylsalicylic acid, who unwittingly took a dose of the drug in the form of an "asthma powder" and died as a result of the ensuing shock. Dysart<sup>11</sup> reported a case of asthma in which the patient knew she was sensitive to acetylsalicylic acid but who nevertheless deliberately took 5 grains (0.3 Gm.) of the drug and was dead within ten minutes. Francis, Ghent and Bullen<sup>12</sup> observed a case that illustrates still a third fashion in which the asthmatic patient who is sensitive to acetylsalicylic acid may come to grief. Their patient had had a previous unfortunate experience with acetylsalicylic acid, once having had an asthmatic attack of four days' duration as a result of taking 5 grains of the drug. Sometime later, having a severe attack of asthma, the patient sought relief at a hospital where he had not been treated previously. Ephedrine, epinephrine, amytal and other remedies were administered without much effect. When 10 grains (0.65 Gm.) of acetylsalicylic acid was given, the patient promptly went into a condition of shock and died thirty hours later despite all therapeutic efforts, including the administration of oxygen.

Violent bronchial asthma occurred in nine of fifteen cases of sensitivity to acetylsalicylic acid in Cooke's series; in one case almost fatal asphyxia was the result. Estimating that 10 per cent of all asthmatic patients are allergic to acetylsalicylic acid, van Leeuwen was of the opinion that these patients should be regarded as a special subgroup among the asthmatic. He noted that almost without exception they had severe asthma and were sensitive to many things besides acetylsalicylic acid. He found the treatment of these patients for asthma to be disappointing. Epinephrine, he stated, is "remarkably ineffective"; alcohol and morphine he found to be more useful.

Among the patients in our series who were asthmatic, three stated that their first attack of asthma had followed the use of acetylsalicylic acid. Van Leeuwen also observed patients who experienced their first asthmatic attack following ingestion of a tablet of acetylsalicylic acid and who continued to have frequent, even daily, attacks of a very severe nature thereafter. Asthma alone occurred in thirty-eight of the sixty-two cases (61 per cent). In combination with urticaria, vasomotor rhinitis or abdominal cramping, asthma occurred in five (8 per cent) additional cases. In only one case in our series was the asthma described as "mild wheezing"; in all others it was very severe. Palpitation was a distressing accompaniment of asthma and, in a few instances, cyanosis was present. One patient had learned from

experience to avoid acetylsalicylic acid but had had very severe asthmatic reactions, necessitating hospitalization, from taking nationally advertised headache and cold remedies which apparently contained quantities of this drug.

The duration of these asthmatic responses to the administration of acetylsalicylic acid varied from two hours to two days. Duke<sup>7</sup> stated that the reaction can last for from several days to one or two weeks or more. Cooke referred to one patient whose attack was prolonged for three weeks, but he stated that the attacks usually last from eight to thirty-six hours.

A recent experience with a patient who had an alarming attack of asthma after the administration of acetylsalicylic acid is as follows:

A farmer, aged 43, had had asthma for eighteen months. It came on after years of colds and prolonged coughing spells with expectoration. Mild at first, it became severe six months prior to his admission and, when first seen, he required epinephrine at least once daily and twice at night for relief of symptoms. He had lost 47 pounds (21 Kg.). He had had nasal congestion for years and a brief episode of eczema six years previously. A sister had had asthma.

Physical examination disclosed two pertinent features; the lungs were full of wheezing râles, breathing was labored, and both sides of the nose were filled with polyps. Sensitization tests were entirely negative after intradermal injections of airborne and food antigens. Stereoscopic roentgenograms of the pulmonary fields were essentially negative, and roentgenograms of the sinuses revealed polyps in the left frontal sinus, right and left ethmoids, and left antrum.

The patient was sent to the hospital for removal of the nasal polyps and for investigation of the sinuses. During the night before operation the patient was given 10 grains (0.65 Gm.) of acetylsalicylic acid. He had taken this drug but rarely in the past and remembered no ill effects from its use. Within thirty minutes after he took the drug this time, however, very severe and alarming asthma developed associated with cyanosis, perspiration, nausea and prostration. The pulse rate rose to 120 beats per minute and respirations rose from 18 to 32. Epinephrine failed to influence the asthma even when administered repeatedly at intervals of twenty minutes. Morphine gave but slight relief.

When he was placed in a tent containing 80 per cent oxygen, the patient's color improved somewhat but no other change could be noticed. The cervical musculature was contracted and the head was thrown back, making an almost straight tube of his trachea, pharynx and mouth. The mouth was open and dry and the breathing was very labored. The patient's condition became alarming; exhaustion was apparent. About thirteen hours after the onset of the acute asthma, a helium-oxygen mixture was administered, which definitely eased the effort of breathing but did not influence the asthma. Slight, although definite, improvement was noticed two and a half hours later and, in the following two hours, recovery seemed assured. The administration of helium was discontinued after almost four hours, but the patient was kept in an oxygen tent until the following morning, approximately thirty-two hours after the onset of the attack. Three days later bilateral antral windows were made and the nasal polyps were removed. Convalescence from this operation was uneventful.

The ineffectiveness of epinephrine and morphine in this case is characteristic of the more severe reactions to acetylsalicylic acid experienced by other patients in the series. It would seem that relief is obtained only when the effect of the drug wears off.

Vasomotor rhinitis: Typical, although severe, symptoms of vasomotor rhinitis occurred in three cases as a result of patients taking acetylsalicylic acid; it occurred in combination with asthma in two other cases. One patient experienced continuous sneezing and blockage of the nose and another described her reaction as a

effect on the intestinal flora of white rats. The exact explanation for the action of banana, apple and raisins is not apparent, but it is quite probable that the carbohydrate and mineral contents of these fruits are of prime importance in their ability to establish an intestinal flora rich in *Bacillus acidophilus*.

**Bacilluria Caused by Bacterium Alkalescens.**—Snyder and Hanner present a case of continued bacilluria, at times accompanied by a definite though mild pyuria, which was apparently caused by *Bacterium alkalescens*. The organisms fermented dulcitol and were agglutinated by known acid concentration as contrasted with the negative reaction of *Bacterium dysenteriae* (Flexner) to these tests. On the basis of these results and the negative serologic relation with the Flexner type the strain was identified as *Bacterium alkalescens*. This bacilluria has existed now for nearly two years. The infection did not respond to oral administration of methenamine and sodium acid phosphate. However, the child has developed normally and in recent months has seemed in better health than ever. She suffers little from enuresis or even frequency of urination in the daytime. In all likelihood the infection was an ascending one because the organism was found in the stool. The species is apparently saprophytic in nature but under some circumstances may develop parasitic properties such as were displayed in this case.

**Ionization and Allergy.**—Alden points out that ionization in no way alters the fundamental physiologic characteristics of the individual which make him allergic and that it even decreases for only a relatively short time the ability of the nasal cells to combine with and be affected by their offending allergens. What it does is, by a mechanical change, to render the nasal mucosa less able to produce disagreeable obstructive and secretory symptoms in response to either external irritation or vasomotor stimuli. Desensitization is still the method of choice in the treatment of this condition, ionization being reserved for patients in whom the obstructive and secretory symptoms are predominant and in whom the mechanical relief to be expected is more than commensurate with the tissue damage incident to the ionization. Asthma has not been lessened after ionization except in a few cases, in which the author is sure that the improvement was due to the relief from nasal obstruction rather than to any change which the treatment brought about in the allergic status of the patient.

**Surgical Treatment of Scleroderma.**—Leriche and his colleagues discuss the rationale for the conception that the sympathetic apparatus is of pathogenic significance in certain forms of scleroderma and therefore that sympathectomy is indicated as a therapeutic procedure. In this so-called Raynaud-scleroderma type of syndrome, histopathologic studies reveal definite vascular changes and clinical investigations show evidence of pathologic hypertonus of the arterioles. In the thirteen cases of scleroderma in which sympathectomy was performed, improvement followed operation in approximately two thirds of the cases. Therefore a disturbance in the equilibrium of the sympathetic apparatus is not the only or even the most significant factor in the pathogenesis of scleroderma. That a chronic hyperfunction of the parathyroids is of pathogenic significance and that parathyroidectomy is indicated as a therapeutic procedure is discussed in detail. Clinical and experimental investigations clearly demonstrate a definite disturbance in calcium metabolism, thus reflecting exaggerated physiologic function of the parathyroids. Of the thirteen cases of scleroderma in which the authors performed parathyroidectomy, improvement to a greater or lesser degree followed operation in twelve. Two of the patients, examined two and five years respectively after operation, could be considered cured. All the patients had rather severe and generalized forms of scleroderma. Only one patient was considered to have shown no improvement, although amelioration was observed immediately after operation, but the patient died two months later of the complicating Addison's disease. The authors consider parathyroidectomy the procedure of choice in the treatment of scleroderma. Clinical and experimental evidence supports the view that a chronic hyperparathyroidism does exist in scleroderma, and parathyroidectomy seems to ameliorate the condition. Sympathectomy may be combined with parathyroidectomy in cases characterized by symmetrical lesions, especially of the extremities, and in those in which typical vasomotor disturbances are present.

"terrible spell of hay fever." Bolt<sup>13</sup> and Macht<sup>14</sup> described nasal congestion as well as other symptoms following ingestion of acetylsalicylic acid in persons hypersensitive to the drug.

**Urticaria and angioneurotic edema:** The urticarial and angioneurotic edema-like reactions from the ingestion of acetylsalicylic acid were usually very distressing. Severe urticaria and angioneurotic edema following the ingestion of this drug by individuals hypersensitive to it are described frequently in the literature.<sup>15</sup> Edema of the glottis, tongue and throat also occurs occasionally.<sup>16</sup>

Coca<sup>1</sup> felt that acetylsalicylic acid is one of the most common causes of angioneurotic edema. Twelve patients (19 per cent) in our series reacted severely, with urticaria and angioneurotic edema. In addition, one patient with urticaria had severe abdominal cramps, and two others had asthma with urticaria. Severe palpitation sometimes accompanied the urticaria, and one patient had a temperature of 100 F. One patient, a man, had a more severe reaction of this type, with severe urticaria, "giant hives," and violent burning all over his body, which was almost unbearable in the scalp and on the palms and soles and occasionally was accompanied by purpura.

The patients in this group offered vivid descriptions of their own reactions to acetylsalicylic acid: One mentioned swelling of the face and bulging of the eyes; several mentioned swelling of the throat or tongue, and one patient's thumb was "twice normal size." Another patient described her face, after she had ingested one 5-grain tablet of acetylsalicylic acid, as a "terrible sight"; her "whole face was swollen," her eyes were "swelled shut" and her lips were "swollen and rolled out." A man who reacted with severe urticaria every time he took acetylsalicylic acid since the age of 15 years said that on one occasion he had been so gravely ill after taking it that he was "brought home to die."

No instance of dermatitis medicamentosa following the taking of acetylsalicylic acid was included in this series. The reactions to the drug in cases of dermatitis medicamentosa are delayed and usually mild, and the subsequent use of the drug does not provoke a repeti-

tion of symptoms. Clearly, the mechanism is entirely different from that of true hypersensitivity to drugs in the atopic sense.

**Abdominal pain:** Three patients in the series experienced abdominal pains, described in each case as "very severe abdominal cramps":

One patient, a man, aged 45, whose allergic complaints were asthmatic bronchitis and vasomotor rhinitis, stated that forty-five minutes after taking acetylsalicylic acid by mouth he experienced "swelling up of the stomach," abdominal "spasms" and severe asthma. He volunteered the statement that he would never take acetylsalicylic acid again. He was not sensitive to any other drug as far as he knew and his skin tests to common allergens were negative. He was not given a skin test with acetylsalicylic acid.

A second patient, a girl, aged 20 years, whose familial and personal history were negative for allergy, took 10 grains (0.65 Gm.) of acetylsalicylic acid and, about an hour later, experienced severe abdominal cramping, with swelling of the face, tongue and fingers. Slight erythema and fever (100 F.) were noted. The worst of the reaction lasted about three and a half hours, but the swelling of the fingers persisted for twelve hours. This patient estimated that she previously had used the drug only six or seven times, always without untoward effects.

The third of these patients was a woman, aged 55, who had had hay fever, urticaria and angioneurotic edema, and she had a positive familial history of allergy. Skin tests were positive for pollens and negative for other air-borne and food antigens. She previously had used acetylsalicylic acid with no bad results until, for no reason known to her, she began to experience marked salivation about an hour or two after taking the drug. With this salivation she "doubled up" with griping, colicky pains and abdominal contractions. This occurred several times, always in the same way. Taking the drug before going to bed, she would go to sleep only to be awakened by these symptoms. It was her practice to get up then and to drink a quantity of sodium bicarbonate in water, which relieved her distress and permitted her to return to sleep, only to be reawakened by pain, necessitating the use of more soda. She stressed the fact that soda gave only temporary relief until the attack wore off of its own accord.

As an emergency treatment the effect of soda in this case was very useful and should be tried in others. This will be referred to later when the treatment of patients with reactions to acetylsalicylic acid is considered.

It will be noted that external manifestations of edema or urticaria were encountered in one of the three patients who had abdominal pain, which lends some support, therefore, to the theory that the abdominal pain in such cases is due to edema of some portion of the gastro-intestinal tract or peritoneum. Does the marked salivation noted by the third patient indicate reflex stimulation of the salivary glands from abdominal irritation or from hypersensitivity of the nervous control of the salivary glands to acetylsalicylic acid? A similar instance of salivation and abdominal pain following the ingestion of acetylsalicylic acid has been reported by Macht.

**Purpura:** Four references to purpura-like reactions after the ingestion of acetylsalicylic acid were found in the literature. Hirschberg reported the case of a man who had severe, generalized urticaria, angioneurotic edema and nasal congestion following ingestion of 1 Gm. of the drug. Later, raised red spots the size of a dime appeared on his face, neck and mucous membranes and disappeared after four days. A very similar case has been reported by Otto. Karunaratne described an erythematous rash over the face and arms of a man, aged 32, which resulted, together with cyanosis, asthma and edema of the face and neck, from the ingestion of 10 grains (0.65 Gm.) of acetylsalicylic acid. The rash subsided in three days. A similar reaction to taking the

**Paratyphoid Infections of Respiratory Tract.**—Maxwell calls attention to an acute infection of the chest of definite etiology, which is easily overlooked and which can be recognized with certainty if only the possibility of its existence is kept in mind. Two illustrative cases are presented. The clinical features of paratyphoid infection, in cases in which the symptoms are predominantly thoracic, are by no means characteristic, but certain signs should lead one to suspect it. 1. The cough is out of proportion to the physical signs in the chest, and it is usually ineffective. 2. The patient is much more toxic than are other patients who have one of the commoner types of respiratory infection with similar physical signs. 3. Headache, insomnia and sweats appear to be common, and mental confusion and a stuporose condition are very significant. 4. The diagnosis is simple if the blood for the Widal reaction is taken after the eighth day of the disease. 5. Associated abdominal changes are not pronounced, and, perhaps for this reason, the prognosis appears good. From the study of these and other similar cases the author feels safe in predicting an illness of approximately six weeks, with a good prognosis. Treatment need not be so strict as it is in true typhoid infections and should consist in giving large quantities of fluid, preferably fruit juices, with as much dextrose as the patient can be persuaded to take. For the headache, insomnia and other severe toxic symptoms it may be desirable to give morphine in full doses for as long as may be necessary. The treatment of the irritating cough may be difficult, for the usual sedatives have little effect, and it is best to prescribe a linctus containing heroin, even in the early stages of the illness.

**Inhibition of Ovulation by Antigonadotropic Serum.**—Parkes and Rowlands found that antigonadotropic serum prepared by prolonged injection of rabbits with chemically treated ox anterior pituitary extract inhibits the ovulation-producing activity of the antigenic extract itself, of similar extracts of horse pituitary, and of saline suspension of fresh cow and sheep

anterior pituitaries. The serum is less effective in inhibiting the activity of human urine of pregnancy extracts, but it is far from ineffective. This serum, given intravenously to rabbits immediately after mating, inhibits the ovulation which would otherwise occur in from ten to twelve hours and may therefore be said to effect passive immunization against the secretion of the rabbit's own pituitary. There is thus no suggestion of species specificity in the antiovarian action of this serum.

\*Hemorrhagic Aleukia Following Oral Application of Acetarsone: Two Cases. P. Émile-Weil, H. Menetrier and C. Polak.—p. 109.

**Periodic Hydrarthrosis of Knee.**—Periodic hydrarthrosis of the knee always creates a difficult problem. It is an obstinate disorder resembling Quincke's edema. May and his associates had under their observation a case affecting the left knee and which, for twenty years, made its regular appearance twice a month. The knee was not inflamed and was painless, and the general condition of the patient was not affected during the swelling. Not even the roentgenogram showed any changes. Movements were not limited; the quadriceps and the inguinal glands were intact. One puncture produced a lemon-like, dense fluid containing polymorphonuclears and lymphocytes in equal numbers, but no eosinophils. Its refractometric index was 44, which corresponds to about 36.81 of albumin per thousand. Eight roentgen treatments were given to the external and internal aspects of the left knee. The dosage was 225 roentgens with 25 cm. spark gap, 2 milliamperes of current and 6 mm. of aluminum filter. The effect was remarkable and in the following ten months the patient had no recurrence whatever. The authors believe that theirs is the first example of successful roentgen treatment of periodic hydrarthrosis and they are reminded of a theory advanced by Hildebrand, who thinks that in such cases there is an excessive sensitivity of the nervous fibers of the synovia and who declared that the sedative action of roentgen rays would be logical.

**Hemorrhagic Aleukia.**—Émile-Weil and his collaborators had under observation two cases of chronic enteritis which were treated by oral administration of acetarsone. The first patient received a total of 10 Gm. in two months. A hemorrhagic and anemic state made its appearance ten days later. Soon the number of red cells dropped from 1,500,000 to 900,000 in spite of repeated transfusions and injections of liver extract, and there was an all round leukopenia. Puncture of the bone marrow showed a great drop in plastic reaction. After five months the patient recovered and showed only a slight anemia (4,000,000) and some diminution of the granulocytes. In the second case acetarsone was administered more rapidly in spite of occult hemorrhages. The erythrocytes fell from 1,300,000 to 600,000, but with a higher color index. The granulocytes fell to 15 per cent, but without marked leukopenia. Platelets were fewer than 500. The bone marrow showed a strong normoblastic and myeloid reaction, which rendered the prognosis favorable. However, furuncles and a staphylococcal infection undoubtedly contributed to the fatal issue. In both cases the pictures of the bone marrow were misleading. These accidents are rare, since Sézary conducted without such mishaps thousands of acetarsone treatments in patients having dementia paralytica. From the physiologic point of view of aplastic lesions in the marrow it may be stressed that acetarsone is a pentavalent aromatic derivative of arsenic acid and is just as capable of causing hematic injuries as are the trivalents. In fact, the authors have seen a little girl treated with tryparsamide whose case, from the symptoms, appeared hopeless. But she recovered from the anemia, which was not cryptogenic but essential. The probable truth is that these cases are not due to intoxication but to intolerance accompanied by a possible secondary infection.

drug had occurred three years previously. Reed has reported the case of a man, aged 36, who took 5 grains (0.3 Gm.) of the drug, vomited a half hour later, and was cyanotic and severely asthmatic two and a half hours later, his face being edematous and his nose congested. Recovery occurred after five hours, but the next day a papular, purpuric rash was noted over his trunk. The patient had experienced a similar reaction two and a half years before.

Two of our patients noted submucosal or subcutaneous hemorrhages after the ingestion of acetylsalicylic acid:

A woman, aged 50, who had a positive familial history of allergy and who herself had hay fever and migraine, had noted repeatedly that the ingestion of even "tiny amounts" of acetylsalicylic acid resulted in subcutaneous hemorrhages in the hands and legs, together with submucosal hemorrhages in the mouth and throat. She also speculated on the possibility of the repeated ingestion of this drug for headaches, which she was having almost daily at that time, being responsible for her metrorrhagia and menorrhagia. Hysterectomy had been performed because of hemorrhage but no organic lesion had been found in the uterus after it was removed. Realizing that purpura always followed the taking of acetylsalicylic acid in her case, she discontinued its use and had no further trouble until she took a dose of a nationally advertised antacid mixture containing acetylsalicylic acid, when she again had purpura.

The second patient, a man, aged 58, who was definitely allergic (vasomotor rhinitis, asthma, urticaria, food allergy) and who had a positive familial history of allergy but for whom all skin tests were negative, found that from twenty to thirty minutes after taking acetylsalicylic acid by mouth, severe generalized urticaria of the giant type would develop, and occasionally vesicles and definite subcutaneous hemorrhages also would develop. Epinephrine subcutaneously gave some symptomatic relief.

**Angina pectoris syndrome:** A type of reaction which we have not observed but which is of great interest is that reported by Shookhoff and Lieberman. These authors observed three cases in which the ingestion of acetylsalicylic acid was followed by viselike pain, of typical coronary distribution, accompanied by a fall in blood pressure. Urticaria also developed in two of the cases. One patient was given acetylsalicylic acid while under observation, and transient electrocardiographic changes were noted (prolongation of PR interval in derivation II, distinct notching of S in derivation II, increased amplitude of S in derivation III, and inverted T wave in derivation III).

#### DIAGNOSIS

The diagnosis of hypersensitivity to acetylsalicylic acid is usually made accidentally and in an obvious fashion by the patient or his physician. The very real dangers of reactions to acetylsalicylic acid among patients with asthma make it very much worth while to be able to determine such hypersensitivity by means other than giving the drug by mouth. Skin testing, unfortunately, is both inefficient and potentially dangerous. Cooke stated that positive cutaneous reactions will not be obtained except in those cases in which urticaria is the clinical manifestation of the hypersensitivity. He further observed that complete absence of skin allergy, with hypersensitiveness limited to the respiratory mucous membranes, occurs only with drug allergy and particularly with hypersensitiveness to acetylsalicylic acid. Van Leeuwen, working with asthmatic persons allergic to acetylsalicylic acid, found that both cutaneous and intracutaneous skin tests with foods were always negative.

Other investigators<sup>7</sup> have warned against the dangers of skin testing, particularly by the intracutaneous technic, in cases in which patients are hypersensitive to acetylsalicylic acid. Cooke related a case in which a severe constitutional reaction lasting three days followed the intradermal injection of  $\frac{1}{10}$  grain (0.006 Gm.) of acetylsalicylic acid. Only two of our patients (both of whom had nasal polyps) were tested with acetylsalicylic acid: scratch tests with a 1:1,000 solution of acetylsalicylic acid resulted in no reaction in one case, in which the patient gave a clinical history of severe asthma lasting two days following ingestion of the drug, and in a grade 1+ reaction in the other, in which the patient experienced a severe urticarial reaction following ingestion of the drug.

From the purely clinical standpoint, a skin test with acetylsalicylic acid adds very little to the care and study of the patient known to be sensitive to the drug, and the risk of indiscriminate testing in these cases is greater than the value of the test.

In an effort to avoid these dangers, and likewise to provide a method of testing more reliable than the cutaneous methods, Duke has suggested a very simple procedure. A small speck of acetylsalicylic acid is placed in the suspect's mouth. If the individual is allergic to the drug, symptoms such as cough, asthma, itching or edema should appear within one minute. If they do, any of the drug remaining in the mouth is immediately destroyed by rinsing the mouth with a dilute acid solution (vinegar). Duke reported the use of this test with positive results in three cases. We have employed Duke's technic in too few cases to comment on its value at this time.

Coca and Grove<sup>17</sup> were unable to demonstrate the Prausnitz-Kuestner reaction with the serum of patients sensitive to acetylsalicylic acid and quinine even though some of them manifested positive cutaneous reactions.

Although but two of our patients were skin-tested with acetylsalicylic acid, most of them were tested with the common air-borne and food allergens. Excluding those sensitive to pollen, it seems characteristic of the group that the skin tests were frequently negative. Twenty-three (37 per cent) had entirely negative results from all the allergens employed in each case. Positive or questionably positive tests, exclusive of pollens, were found in thirteen cases. Seven patients reacted to food antigens, seven to orris root, seven to feathers, seven to danders, and one to kapok. Excluding pollens, reactions of grade 3+ to orris root and feathers were the greatest reactions obtained.

#### TREATMENT

It has been pointed out<sup>18</sup> that the best treatment for patients who are hypersensitive to drugs is absolute avoidance of the drug. To the patient who has experienced a severe reaction, of whatever type, from the ingestion of acetylsalicylic acid, it hardly is necessary to emphasize the importance of avoiding the drug entirely, even in minute quantities. One not infrequently hears such patients solemnly state "I will never take another dose of aspirin." But such an individual, in spite of all his good intentions, runs two risks: (1) that he will take the drug or be given it unknowingly in some prescription or proprietary remedy or (2) that some one unfamiliar with the severity of the

**Anatomopathologic Modification of Pelvic Sympathetic in Sclerocystic Ovaritis.**—Spirito states that the pathogenesis of sclerocystic ovaritis is hormonal. Neuroma-like formations may exist at the hilus of the sclerocystic or the normal ovary. The anatomic alterations of the pelvic sympathetic which are present in sclerocystic ovaritis are secondary to the sclerosis. They may be due to sclerosis of the nerve or fibrils or to compression of the nerve by nearby sclerosed tissues. The alterations of the pelvic sympathetic are the cause of the pain, which is the most frequent and important symptom of the disease. The treatment consists in resection of the presacral nerve. The resection must be ample to obtain complete and rapid disappearance of the pain. Presacral sympathectomy has an easy technic. Surgical trauma of the ovaries and tubes, which may occur during the performance of an operation, is prevented by sympathectomy. Ovarian and tubal surgical trauma may result in the production of tubal epiploic or intestinal adhesions.

**Sedimentation Speed of Erythrocytes in Ancylostomiasis.**—Bacigalupo and Loretto state that the sedimentation speed of the erythrocytes is not modified in patients suffering from Ancylostoma duodenale infection, regardless of the intensity of the infection. The humoral figures are modified as shown by the presence of eosinophilia. The authors' statements are based on the results of clinical and humoral studies made in five cases.

**Biologic Treatment of Interlobar Suppurative Pleurisy.**—Manguel reports satisfactory results from Mendez's biologic treatment in interlobar suppurative pleurisy. The treatment consists in administration of a daily subcutaneous injection of the content of a vial of a haptene preparation at the infraclavicular region. In making the injection a small amount of the exudate, necessary to relieve pressure, is removed. Pleuritic exudates contain antibodies which, in association with the injected haptenes, make the exudate sterile and control inflammation and the local pathologic condition of the pleura with consequent recovery of the patient. The roentgen study of the thorax during the treatment shows reabsorption of the interlobar suppuration. The injections are discontinued when suppuration stops. The author reports three cases in which recovery occurred.

Casuistics of Pernicious Anemia. Alexandra Iljin.—p. 125.  
\*Testicular Function After Vasectomy. H. Knaus.—p. 129.

**Bismuth Therapy of Tonsillitis.**—Berberich points out that several years ago Monteiro recommended bismuth therapy for tonsillitis. The fact that several other investigators like

wise obtained favorable results with this treatment induced him to try it. He used a bismuth preparation that had been proved harmless in animal experiments and in patients with syphilis. On the basis of his observations he reaches the conclusion that bismuth therapy reduces the duration of tonsillitis to about half the usual time. About twenty-four hours after the intragluteal bismuth injection the temperature subsides to normal, the coatings are cast off and existing edemas disappear. The difficulties in swallowing disappear within six to eight hours. A favorable general condition is usually reestablished after twenty-four hours.

**Testicular Function After Vasectomy.**—Knaus directs attention to the contradictory results of the morphologic examinations of the testes following vasoligation or vasectomy. He admits that at first it may appear strange that typical interventions such as vasoligation or vasectomy cause in some cases complete destruction of the testicular epithelium (congestion atrophy) while in other cases they fail to influence the testes. However, he thinks that whoever is acquainted with the Crew-Fukui-Moore discovery of the specific heat sensitivity of the testes will understand the differences in the testicular changes after the closure of the spermatic duct. He describes investigations on the problem as to whether the spermatogenesis remains unimpaired by vasectomy. If this is the case, the sperm that accumulates in the globus minor of the epididymis must remain fertile. The author's experiments proved the fertility of the sperm of three rabbits that had been subjected to vasectomy more than a year previously. By means of the spermatozoa of these three rabbits, twenty-seven young ones were produced in six female rabbits. He directs attention to a review of the literature on the problem of the testicular function after vasectomy which reveals that in the majority of cases in which the obstruction is made below the efferent ductules the testes remain unimpaired, whereas, if these efferent ductules are obstructed, congestion atrophy and degeneration result regularly. In this connection he recalls certain observations made by Steinach. Regarding the testicular degeneration observed by Spahn in rabbits after vasectomy, the author says that this is not a congestion atrophy but is due to heat injury of the testes, which in turn can be explained by the fact that the testes were in the abdominal cavity. In man, however, the testes do not ascend to the abdominal cavity with its higher temperature but remain in the scrotum, and therefore this testicular degeneration does not occur.

## Ugeskrift for Læger, Copenhagen

98: 1309-1318 (Dec. 31) 1936

- \*Value of Determination of Sugar in Spinal Fluid in Diagnosis of Meningitis and Remarks on Postalbumin Hyperglycorrhachia in Acute Infectious Diseases. N. I. Nissen.—p. 1309.

**Sugar in Spinal Fluid in Diagnosis of Meningitis.**—Nissen found that after administration of large amounts of dextrose in patients with acute infectious diseases and meningitis postalbumin hyperglycorrhachia may be higher than normal, but he emphasizes that no alimentary increase could be established after the intake of ordinary meals with slowly resorbable carbohydrate. On puncture the sugar percentage was slightly higher in the first portion emptied than in the last, and in accord with this the suboccipital fluid in tuberculous meningitis contained somewhat less than the lumbar fluid. The diagnostic value of sugar in the spinal fluid was tested in 529 patients, partly normal, partly with meningitis or meningeal irritation. Of 282 patients with benign disturbances of the meninges (acute anterior poliomyelitis, encephalitis, "meningitis serosa benigna"), only three showed values under 40 mg. per hundred cubic centimeters. Of thirty-one with malignant disorder of the meninges (tuberculous meningitis), twenty-eight gave values under 40 mg. per hundred cubic centimeters. The boundary between benign and malignant meningitis is thus established at 40 mg. per hundred cubic centimeters. Normal values appear only in the earliest stages of tuberculous meningitis. Determination of the sugar in the spinal fluid is of even greater diagnostic value than the cytologic examination and the determination of the albumin content.

reaction experienced by him will urge him to take it because "one tablet of aspirin has never hurt any one." Should that well meaning but uninformed individual be present to witness the result of his careless advice, he would not be likely to question the next person's statement that acetylsalicylic acid or some other drug or food made him ill. The patient known to be sensitive in this way to acetylsalicylic acid should also be told of the proprietary medicines in which he can expect to find it. He will then do the rest. He should also be told that "acetylsalicylic acid" and "acidi-acetylsalicylici" appearing on prescriptions are "aspirin."

Widal<sup>19</sup> and others have reported that hypersensitivity to a drug (antipyrine) may be overcome by feeding small amounts of the drug first. Coca,<sup>1</sup> however, was of the opinion that hyposensitization with acetylsalicylic acid is "unsatisfactory and because of the risk involved should not be undertaken except under compulsion of absolute necessity." Van Leeuwen has expressed a similar opinion against desensitization with acetylsalicylic acid.

*The Attack.*—The treatment of the patient with a reaction following the ingestion of acetylsalicylic acid is chiefly symptomatic and dependent on the nature and severity of the reaction. Repeated hypodermic injections of epinephrine will in most instances be found useful, although entirely ineffectual for some of the worst reactions. The experience of one of our patients in obtaining very satisfactory temporary relief by the repeated ingestion of a solution of sodium bicarbonate suggests that it be tried in other cases. Since another of our patients stated that she was unable to take sodium salicylate as well as acetylsalicylic acid, it is possible that most patients will derive no benefit from this measure. To be effective, the solution of sodium bicarbonate should be given very early, at which time, if there are no contraindications, gastric lavage might also be considered.

If any acetylsalicylic acid remains in the patient's mouth at the time of the reaction, in addition to its prompt removal Duke<sup>7</sup> advised rinsing the mouth repeatedly with a solution containing 4 cc. of dilute acetic acid or vinegar to a glass of water.

Since the majority of patients who are sensitive to acetylsalicylic acid react with violent and prolonged asthma, it not infrequently will be necessary to use oxygen, and possibly a mixture of helium and oxygen,<sup>20</sup> such as was used for one of our patients to reduce the fatigue from hours of asthmatic dyspnea. The use of morphine does not relieve the asthma; it has a depressant effect and it would seem best to omit it in such instances.

*Comment.*—The question as to whether hypersensitivity to acetylsalicylic acid is congenital or acquired is of theoretical and considerable practical importance. Karunaratne reported the case of a man of 32 who, so far as could be determined, had taken acetylsalicylic acid only twice during his life. Both times he experienced violent reactions. We have already referred to similar observations noted by van Leeuwen.<sup>5</sup>

Among our patients there were fifteen who believed that their first encounter with acetylsalicylic acid was followed by an allergic reaction of some sort. Unfortunately, one cannot be certain that these patients had

not taken acetylsalicylic acid previously. They may have taken it as a constituent of a prescription or "patent medicine" when its presence was unsuspected or they may have forgotten the incident of taking it since no extraordinary reaction had followed. Most of our patients, and many of those reported in the literature,<sup>21</sup> had taken the drug many times without ill effect. Coke<sup>22</sup> concluded that this hypersensitivity was always acquired; he believed that it affected those who took the drug in considerable quantity and then went for a long time without taking it. The histories of our patients do not bear this out. Five of them said that they rarely had used acetylsalicylic acid previously; seven had used it occasionally and seven more often still.

In no instance in our series of cases or in those reported in the literature was more than one member of a family sensitive to acetylsalicylic acid. One allergic patient who was sensitive to the drug had a son who also was definitely allergic, but he could take acetylsalicylic acid without any abnormal reaction.

These observations cannot be used to argue for or against the hereditary, as opposed to the acquired, nature of hypersensitivity to acetylsalicylic acid. Presumably a hereditary hypersensitivity need not make itself known until long after birth, at a time when other factors favor its appearance; or it may never manifest itself.

Very little concerning the actual mechanism of drug allergy is known. Van Leeuwen assumed that the allergic action of a drug is only an "augmenter action" on other subliminal reactions going on in the body. Perhaps the most significant observations are those of Landsteiner and Lampl<sup>23</sup> and Landsteiner,<sup>24</sup> who have pointed out that simple chemicals can combine with proteins to form new compounds which have specific immunologic properties.

Sensitivity to drugs is remarkably specific as a rule.<sup>24</sup> An individual may be hypersensitive to one drug such as acetylsalicylic acid and yet take with impunity closely related drugs such as salicylic acid, methyl salicylate and also compounds containing radicals common to acetylsalicylic acid, such as benzoic acid and sodium acetate.<sup>6</sup> It would seem that hypersensitivity may be manifested toward the whole molecule or merely toward radicals or groups of radicals in the molecule.<sup>25</sup> In the case of acetylsalicylic acid, the acetyl group seems to be the one responsible for making it the most common atopen among the salicylic compounds.

Van Leeuwen found that his patients were often sensitive to other drugs, such as phenobarbital, antipyrine, sodium salicylate and barbitol.<sup>26</sup> Of our patients, twenty stated that they knew of no other drug or medicine to which they were hypersensitive, while nineteen mentioned some drug or drugs other than acetylsalicylic acid which, for one reason or another, they could not take. Among the preparations named were quinine, sodium salicylate, acetophenetidin,

epinephrine, cocaine, iodides, aminopyrine, morphine, strychnine, "any coal tar products," and a number of proprietary preparations.

A number of patients found to their sorrow that many proprietary medicines, including a number of so-called asthma remedies,<sup>10</sup> contain acetylsalicylic acid. At the present time among the best known of these preparations are Alka-Seltzer, Anacin, Aspirgum, Calaspirin, Acetidine, Dr. Miles Aspiromint, M. Matte's German Asthma Powder, Empirin Compound, and Etro. Doubtless there are many others. Unfortunately for those who are sensitive to acetylsalicylic acid, the present Food and Drug Laws do not require that the words "acetylsalicylic acid" or "aspirin" appear on the labels for proprietary medicines that contain it.

Coca<sup>1</sup> was of the opinion that "aspirin and the closely related coal tar products are among the most treacherous drugs employed in the therapy of asthma." Duke stated that the effect of acetylsalicylic acid on patients sensitive to it can amount to a "catastrophe in every sense of the word." Our own experience amply confirms these statements.

As a diagnostic test to aid in differentiating rheumatic or infectious arthritis from tuberculous, gonorrheal or syphilitic arthritis and to evaluate the possible therapeutic value of the removal of foci of infection, Wolf<sup>27</sup> has proposed and used successfully what he calls the "aspirin tablet test." In light of our experience and that of others, great caution should be exercised in using this test on allergic patients.

A relationship of obscure etiology but of definite practical importance exists between the presence of nasal polyps and allergic diseases and hypersensitivity to acetylsalicylic acid in particular. Of our sixty-two patients, twenty-one (33 per cent) definitely had nasal polyps. In addition to these, a number of others, particularly those with vasomotor rhinitis, probably had them although no definite record of their existence was made. It is significant that in our series those patients who had nasal polyps responded with the worst reactions to the ingestion of acetylsalicylic acid. Nineteen of the patients who had nasal polyps had severe to grave asthma, one had "terrible hay fever," and one had generalized severe urticaria.

The prognostic importance of the presence or absence of hypersensitivity to acetylsalicylic acid among asthmatic patients with nasal polyps was emphasized by Francis.<sup>28</sup> Basing his conclusions on the case histories of twenty-four patients with asthma whose nasal polyps had been removed in an attempt to benefit the asthma, he formulated these rules: 1. If a patient can take acetylsalicylic acid, removal of nasal polyps will benefit the asthma (ten cases). 2. If a patient cannot take the drug, removal of nasal polyps will make the asthma worse (eleven cases). He further warned against giving acetylsalicylic acid to asthmatic patients who have nasal polyps.

#### SUMMARY AND CONCLUSIONS

Hypersensitivity to acetylsalicylic acid is the most common form of drug allergy, and it is much more common than is generally supposed. A series of sixty-two cases was studied. The condition is more common among females and is limited almost exclusively to persons with a personal or familial history of allergy. Particularly noteworthy is the high incidence of hyper-

sensitivity to acetylsalicylic acid among the asthmatic, especially among asthmatic individuals with nasal polyps.

Asthma, urticaria and angioneurotic edema are the most common forms of reaction to the ingestion of acetylsalicylic acid by sensitive individuals. The asthmatic attacks are prone to be severe, prolonged and resistant to treatment. Fatal reactions have been reported. Other types of reaction which have been observed are vasomotor rhinitis, purpura, abdominal cramps and salivation.

Skin testing should not be employed in the diagnosis of hypersensitivity to acetylsalicylic acid as such tests are both unreliable and a potential source of danger.

Scrupulous avoidance of the drug by the allergic patient is the best treatment for hypersensitivity to acetylsalicylic acid. The presence of acetylsalicylic acid in the formulas of many proprietary medicines makes them a potential source of danger to these patients. Acetylsalicylic acid, however, is a useful and effective drug, and it may be prescribed with relative safety to patients who give no history of personal or familial allergy. It may also be used with caution by allergic patients after ascertaining that it has been used previously by them without ill effect. It should never be administered, however, to asthmatic patients who have nasal polyps.

## DARK ADAPTATION AND VITAMIN A

### A NEW PHOTOMETRIC TECHNIC

P. C. JEANS, M.D.

EVELYN BLANCHARD, M.S.

AND

ZELMA ZENTMIRE, M.S.

IOWA CITY

In 1934 we<sup>1</sup> described a photometric test for detecting moderate degrees of vitamin A deficiency by determining ability to adapt to darkness. The observations that formed the basis of the former report were made with a Birch-Hirschfeld photometer. For reasons discussed subsequently this instrument is not adapted for satisfactory use in the manner employed. Because of the difficulties encountered, a new photometer has been devised especially for the dark adaptation test. It is our purpose in this publication to describe the use of the new photometer and also certain experimental observations that have been made with it.<sup>2</sup>

The new photometric technic makes use of the same basic principles as were described in our previous report. Scotopic vision is observed with relation to exposure to a bright light and to a period in darkness. The observations are made by determining the amount of light necessary for the subject to see three of the five

ELIMINATION OF PHENOLPHTHALEIN IN THE URINE

*Free Phenolphthalein.*—This was found in only 8.5 per cent of the urines of medical students and in 21.5 per cent of the urines of the Cook County Hospital patients. This is probably due to the following two facts:

1. The larger the dose the more frequently does free phenolphthalein appear in the urine (chart 1). A larger proportion of the Cook County Hospital patients than of the medical students received 0.3 Gm. doses of phenolphthalein.

2. We have proof of the fact that bacterial decomposition of the urine liberates phenolphthalein from its conjugated form. Many of the Cook County Hospital specimens were over twenty-four hours old and without preservative.

*Conjugated Phenolphthalein.*—In explanation of the figures in the report, it should be pointed out that these express the amount of free phenolphthalein into which the conjugated form is converted by the prolonged heating after addition of acid. The substance or substances with which the phenolphthalein is conjugated are thought to be sulfate and glycuronate.

Conjugated phenolphthalein was found in every urine specimen examined. In other words, one can tell, by the presence or absence of conjugated phenolphthalein in the urine, whether a person has taken phenolphthalein or not.

The quantity of conjugated phenolphthalein when free phenolphthalein was also present was always greater (with a few exceptions) than that of free phenolphthalein. On the theory that phenolphthalein, after absorption from the alimentary tract, is conjugated as it passes through the liver one can explain the presence of conjugated phenolphthalein when there is no free phenolphthalein or the fact that there is

A detailed study of the quantitative relations of phenolphthalein elimination in the urine and of some of the conditions that influence it will be the subject of a separate paper.

EVIDENCE FROM THE LITERATURE

Zoltan von Vamossy,<sup>6</sup> who discovered the cathartic action of phenolphthalein in the course of an investigation for the Hungarian government to determine whether this substance was sufficiently harmless to

Chart 2.—Relation of quantity of conjugated phenolphthalein eliminated in urine to doses ingested. Each x shows the average of all the observations in the respective zone.

mark adulterated wine with it, concentrated his attention on other possible effects of phenolphthalein on the human body and was unable to discover any. Tunnicliffe,<sup>7</sup> Mendelsohn,<sup>8</sup> Blum,<sup>9</sup> Fleig<sup>10</sup> and many others paid a great deal of attention to the effect of the substance on the kidney, and they arrived at the opinion that it is absolutely harmless not only to the healthy kidney but also to patients with nephritis of various kinds; the contrast was pointed out between it and the unfavorable effect on the kidney of a number of vegetable purgatives, such as colocynth, aloe and anthrapurpurin.

While there is a host of witnesses corroborating the correctness of our observations and the opinion of the critical authors of the textbooks quoted, the question may be raised how it happens that some writers of textbooks report that phenolphthalein has produced albuminuria. A survey of the literature shows that this assertion rests on a few sporadic case reports, most of them dating from the early days of the use of phenolphthalein, when its action was not yet understood and anything that happened after its administration was ascribed to it, and on a solitary and unconfirmed report by Hydrick.<sup>11</sup> Typical of the early case reports are the following:

Blumenthal<sup>12</sup> cites a case of febrile hemolytic jaundice and hemoglobinuria that occurred, accompanied by

Chart 1.—Percentage of cases showing free phenolphthalein in the urine in relation to the dose. The larger the dose, the more frequently does free phenolphthalein appear in the urine. Each x shows the average of all the observations in the respective zone.

more conjugated than free phenolphthalein in the urine in most cases. The exceptions to the rule are probably due to the decomposition of the conjugated phenolphthalein by bacterial action, as all the fourteen specimens (excepting one) that showed this condition came from the Cook County Hospital.

As shown by chart 2, there is some relation between the amount of conjugated phenolphthalein eliminated and the dose ingested. This chart indicated that, the larger the dose, the greater the average amount of conjugated phenolphthalein eliminated.

points of a dice five-spot, or quincunx, punched out of a metal screen, when the light transmitted through the holes is of decreasing intensity from the left to the right of the quincunx. Thus the essential features of the instrument include a bright light, a quincunx screen and a dim light of controllable variability of intensity for illumination through the holes of the quincunx screen.

In the schematic representation of figure 1 are shown some of the features of the new photometer.

Fig. 1.—Schematic representation of the biophotometer.

The bulbs for producing the bright and the dim light are housed within the instrument. The switch in the upper left corner controls the bright light, the dim light and the quincunx screen. When the switch is turned fully forward, the quincunx screen is swung out of the line of vision and the bright light is turned on. Looking into the eyepiece, one sees the frosted glass screen. This screen is illuminated by a 100 watt "daylight" bulb, maintained at a constant intensity of illumination. The light value at the end of the eyepiece is 1.1 foot candles. When the same switch is turned fully backward the quincunx screen is brought into the line of vision, the bright light is turned off and a small bulb is lighted. The light of the small bulb is controlled by a rheostat, the handle of which turns over a numbered dial. As the handle is turned from zero the resistance is increased and the light that passes through the quincunx becomes less intense. When the dial setting is zero, all five of the light spots of the quincunx are visible. As the pointer is turned over the dial and the light becomes dimmer, the two spots on the observer's right disappear. With further turning the middle spot and finally the two spots on the left disappear.

The photometer is equipped with a means for standardizing the voltage used. The distance of the eyes from the light and the quincunx screen is fixed by means of an eyepiece. The quincunx as a whole and the individual holes of the quincunx are larger than in the Birch-Hirschfeld instrument. These changes in the quincunx, together with alteration of the relative intensities of light transmitted through the holes, make the reading easier.

The test may be conducted with a large number of variations. Differences in adaptation may be shown by any one of several technics. A subject who has poor adaptation as shown by one variety of test will have the same abnormality demonstrated by another variety.

The selection of one of these procedures to be used as a standard seems highly desirable. The use of such a standard permits comparison of the results of all observers employing it. After trial of many types of variation, a procedure has been chosen which we believe makes a useful standard.

#### A STANDARD TECHNIC

The photometer is installed in a dark room, which is kept in as nearly absolute darkness as possible throughout the test. Though it is theoretically possible to conduct the test in a lighted room, this is not a practical procedure. Especially with children, a bright light in the room invariably interferes with the test. The eyepiece of the photometer is so shaped that, as the subject looks into the instrument, he can press his head against the soft rubber edge and exclude most extraneous light. It is much less tiring, however, if he is permitted more freedom of motion between readings.

Personal comfort of the subject is considered important. At least between readings, opportunity should be offered for relaxation against a back support. The photometer should be adjusted at an appropriate height for each subject. Any fatigue that may occur to the extent of interfering with the results of the test is not retinal but is in the mental and body processes.

It is necessary that the operator have a source of light in order to read the dial and a time piece. For this purpose a small red light, well shaded, used intermittently as needed, will cause the least amount of interference should some of the light leak around the eyepiece.

The time consumed by the test comprises a total of twenty-three minutes divided into three periods: (1) a ten minute foreperiod in the dark, (2) exposure to the bright light of the photometer for three minutes, and (3) a ten minute period in the dark. Readings are made at the beginning, middle and end of the foreperiod and at the beginning and end of the recovery period, with one or two additional readings in the recovery period between the first and last readings. As soon as the ten minute reading of the foreperiod is made, the subject is exposed to the bright light of the photometer for three minutes. During the time of

Fig. 2.—Plotted readings of a test of a normal subject: 1, foreperiod; 2, light period; 3, recovery period.

the exposure to the bright light, it is important that the subject keep the head closely against the eyepiece; children may try to look over or under the photometer. Attention should be given that the subject does not close his eyes. Care must be taken that the switch which controls the bright light is completely thrown; otherwise the subject looks at the dim light.

Immediately after exposure to the bright light for three minutes the quincunx screen is thrown into position and a reading is made. The test is completed by

vomiting, the day after the taking of a 0.1 Gm. "Purgen" tablet. Cylindruria and albuminuria continued for several days and then disappeared. No other report of any such syndrome following the administration of phenolphthalein is available.

Von Jaksch<sup>13</sup> mentions in his book on "Die Vergiftungen" a "verbal" report by a Dr. Wiener of a woman who took large doses of "Purgen" and who suffered from pain in the colon with spastic contraction and had frequent bleeding from the urinary bladder. That something else than phenolphthalein must have caused the "frequent bleeding" seems again obvious, as reports of other such cases are lacking.

Fürbringer<sup>14</sup> reports the case of a woman, aged 59, convalescing from erysipelas, who, after taking 0.6 Gm. of phenolphthalein, developed a drastic diarrhea and whose urine contained albumin and casts. This the author, who had not seen the patient previously, ascribes to the taking of the phenolphthalein, as he does "not know of such late kidney symptoms developing frequently after erysipelas." The urine still contained a trace of albumin in the third week after the taking of the phenolphthalein. That erysipelas is much more likely to be responsible for such continued albuminuria than the phenolphthalein seems obvious in accordance with our present understanding of the two possibilities.

The "law of chance" must cause a dose of medicine that is used with a high degree of frequency to be followed by unexpected symptoms that would also have occurred had the medicine not been taken. When a drug has a real tendency to produce a certain untoward manifestation, the frequent use of the drug will invariably cause recurrences of the phenomenon; and, the more extensively the drug is used, the more common will be the manifestation. This is illustrated by the phenolphthalein eruption, of which, though it is in point of fact comparatively rare, we now have a large number of cases on record.

A paper by J. L. Hydrick was read in 1914 before the American Society of Biological Chemistry which was abstracted in the *Proceedings*. He reports an unbroken series of twenty different individuals in each of whom the subject's urine showed no trace of albumin before the taking of the phenolphthalein, and in each and every one of whom positive tests for albumin were secured in the twenty-four hour specimen of urine ("a twenty-four hour specimen is important"), collected after the administration of 1 or 2 grain (0.065 or 0.13 Gm.) doses of phenolphthalein. This finding of Hydrick's is diametrically opposite to the results of all other students of the question, as well as our own. It has never been confirmed. Hydrick's original paper, which he wrote while he was an undergraduate at Jefferson Medical College, was never published excepting in abstract, because he had written in the report to the society that what he had done was not for publication but to call the attention of the society to the fact that this was a subject which should be investigated thoroughly.

Dr. John L. Hydrick, in a personal communication of Nov. 8, 1936, graciously states: "It is, of course, impossible for me to say what possible errors of technic, or what special circumstances produced the results in my experiments that were interpreted by me, and by several others who saw some of my experiments, as evidence of

albuminuria after taking phenolphthalein. . . . It is possible that the phenolphthalein of 1914 was not so pure as that of 1936."

If a preliminary twenty-four hour specimen of urine was not examined, there are at least two pitfalls one might stumble into: 1. In orthostatic albuminuria a morning specimen of urine is free from albumin, while a twenty-four hour specimen contains it. 2. When a twenty-four hour specimen of urine is preserved with toluene or xylene and it is not clarified by filtration, Robert's ring test is positive, giving a false albumin reaction; and addition of alcohol is of no differentiating value, because alcohol by itself produces a ring with Robert's reagent, obviously the result of precipitation of magnesium sulfate.

#### CONCLUSIONS

1. Medicinal doses of phenolphthalein do not produce albuminuria.

2. While free phenolphthalein is generally absent in the urine of individuals who take a small medicinal dose of phenolphthalein, conjugated phenolphthalein is always present.

3. The larger the dose, the greater the percentage of individuals passing free phenolphthalein in the urine, and the greater the average amount of conjugated phenolphthalein eliminated.

#### TRANSITORY HYPERGLYCEMIA AND GLYCOSURIA IN ACUTE CORO- NARY OCCLUSION

KEN W. BLAKE, M.D.

LOS ANGELES

The report of a transitory hyperglycemia and glycosuria occurring in a patient with acute coronary occlusion follows:

M. E., a white woman, aged 52, entered the Cedars of Lebanon medical ward, service of Dr. H. H. Lissner, at 3 a. m., Jan. 16, 1936. She complained of cutting pain in the precordium radiating down the inner aspect of the left arm, nausea and vomiting. The patient had had a known hypertension for several years; according to her attending physician, and during the past year had noted a mild pain of a similar character which had been induced by exertion, excitement or heavy eating and relieved by rest. These pains had been gradually becoming more severe and frequent. On the day previous to admission she had felt somewhat weak and about 10:30 p. m., while resting, the onset of the pain had occurred very suddenly. She was apparently in shock when seen by her attending physician and was sent immediately to the hospital. The family and past history were essentially irrelevant. On entrance to the hospital the patient, who was somewhat obese, was noted to have an ashy gray pallor, was slightly cyanotic and appeared to be suffering with rather intense pain. The pulse was 90, the temperature 98 F. and the respiratory rate 25. The pupils reacted to light and in accommodation. The heart was enlarged to the anterior axillary line, the apex being in the fifth interspace. The tones were distant and muffled. The rhythm was normal. No friction rub was heard. The blood pressure was 100 systolic, 82 diastolic. The lungs were clear, the abdomen presented no abnormalities, and there was no peripheral edema. An electrocardiogram taken several hours later revealed a simple tachycardia, very severe myocardial damage, disturbance of the interventricular conduction and T wave changes in all four leads diagnostic of acute coronary occlusion. The leukocyte count was 12,000 per cubic millimeter of blood. The blood nonprotein nitrogen was 49 mg. per hundred cubic centimeters and the blood Wassermann reaction was negative. The sedimentation time was decreased from 120 minutes normal to 30 minutes. Urinalysis revealed a specific gravity of 1.037, a

making readings every two and one-half to three minutes for a ten minute period. Readings made more frequently tend to tire the subject, with a possible result of causing the later readings to differ somewhat from those which otherwise would have been obtained.

#### MAKING READINGS

Readings are made by turning the rheostat handle over the dial until only two spots are seen and then turning it slowly back until the third spot is again just

Fig. 3.—Plotted readings indicating the range of values found when a large group is tested.

visible. This is the end point and the dial reading is recorded. In all instances the dial pointer should be turned slowly enough to allow for the lag which occurs between its turning and the ability of the subject to see the spots. Readings should be made, if possible, within thirty seconds; a longer period is tiring and more light may be required to see the spots.

Readings in the foreperiod are more simply made than those in the recovery period. The first reading in the recovery period is an important one and the most difficult to obtain accurately. Considerable practice is required. A very rapid adaptation occurs, which seems to slow down between twenty and thirty seconds from the time the bright light is turned off. The reading should be made between twenty and thirty seconds. For making this first reading in the recovery period the light control is turned slowly from zero until only two spots are seen. If twenty seconds has not elapsed when two spots are seen, it is best to stop turning the rheostat control and to keep inquiring how many spots are seen until the twenty seconds passes. If at twenty seconds the third spot has reappeared, the control should be turned until only two are seen. This procedure eliminates the after-image of the center spot. The point at which only two spots are seen should be found as soon after twenty seconds as possible. The rheostat handle is then turned back to the end point of three spots. The third spot should be plain enough so that the subject is certain it is seen. Blinking or

flicker of the spots is sometimes observed. However, if the subject is certain that three spots are seen, the end point has been reached. Flicker is more often present in those who have poor dark-adaptation. As the rheostat handle is turned slowly from zero, the subject will see three or more spots, perhaps, until the dial reads 35, at which point he sees two; but when the handle is turned back until three are seen again, the reading may be 20. Occasionally, individuals are encountered who have more than the usual lag of vision; it may be so marked that several tests must be made if a significant first reading is obtained.

For making readings subsequent to the first one in the recovery period the light control need not be turned back to zero but may be started from the place it was left at the previous reading. The time of the reading is recorded as that of the nearest half-minute at the end of the reading.

#### COMMENT ON THE READINGS

The intensity of the light transmitted through the center hole of the quincunx is known for all dial readings. The readings in terms of the dial settings are converted to light values in millifoot candles and plotted to make a graphic record. Such a record is shown in figure 2. In this chart the three phases of the test are shown. The plotted points represent the amount of light required to see just three of the five spots of the quincunx. The readings in the foreperiod represent the adaptation in the dark after exposure to the light of chance environment preceding the test. These readings do not have as great significance as those of the recovery period. The chief purpose of the foreperiod is to eliminate the effect of differences in preceding environmental light intensities and to bring all subjects to a more nearly equal basis for the test. The initial reading varies at different times with the same individual, the variation depending on the intensity of the light to which the subject was exposed immediately preceding the test. In some instances the first reading is informative when considered in relation

Fig. 4—Two types of borderline curve.

to subsequent readings. Individuals with poor dark adaptation usually require more light for this first reading than do normal subjects. The reading made in the middle of the foreperiod gives some information, but its greatest usefulness lies in the additional opportunity permitted the subject to become accustomed to the procedure before the more critical readings are made. The reading at the end of the ten minute foreperiod is more significant than the readings which precede.

The readings in the recovery period represent the adaptation in the dark after exposure to the experi-

moderately heavy trace of albumin and positive sugar, and acetone. The patient was put at extreme rest on a 2,000 calory diet containing 235 Gm. of carbohydrate, 60 Gm. of protein and 90 Gm. of fat and was treated symptomatically. January 17, the fasting blood sugar was 244 mg. per hundred cubic centimeters. The same day the temperature rose to 99.6 F. and two days later to 100.2. A friction rub was never heard but January 21 a "gallop rhythm" was audible, which persisted until February 10. The fasting blood sugar was repeated on the twelfth day after admission and found to be 172 mg. By the thirteenth day after admission the urine was sugar free and negative for acetone, although a moderately heavy trace of albumin still persisted. On the sixteenth day the fasting blood sugar was 200 mg., on the twenty-sixth day 141 mg., on the forty-sixth day 139 mg., on the sixty-eighth day 116 mg., and on the seventy-first day 98 mg. per hundred cubic centimeters of blood. Successive electrocardiograms taken at intervals of several days showed progressive changes toward normal in the T waves. January 27, or on the eleventh day after admission, signs of acute congestive heart failure developed and the patient was placed on digitalis and limited fluids. Her condition steadily improved and she was discharged to her home ambulatory March 29, seventy-three days after admission. At no time during her stay at the hospital or before had the patient had insulin. May 5, 110 days after the onset of the occlusion, the fasting blood sugar taken at home was 86 mg. per hundred cubic centimeters of blood.

The report of this case is undertaken for the purpose of emphasizing one of the frequent clinical features of acute coronary occlusion that is often misinterpreted and mistreated—transitory hyperglycemia and glycosuria. It is misinterpreted because the condition is apt to be confused with true diabetes mellitus and mistreated because insulin is often employed in such doses that the blood sugar is rapidly lowered, thereby leading to serious faults in conduction, namely, extrasystoles, auricular fibrillation and bundle branch block,<sup>1</sup> to acute congestive failure<sup>2</sup> or frequently to death.

In a recent survey of seventy-four cases of acute coronary occlusion seen at this hospital which were proved by clinical and electrocardiographic examinations and in which there had been no previously known diabetes, 20 per cent were found to show hyperglycemia or glycosuria shortly after the onset of the occlusion. In all these cases the blood sugar had returned to normal or the urine was sugar free by the end of the convalescence, with no particular steps directed toward this end. In three of these cases, in which a series of blood sugar determinations had been made, the results were quite similar to those of the case reported. The incidence in this series appears higher than one would expect to find, although it is consistent with Edelmann's<sup>3</sup> series in which he found that eleven of fifty-six cases showed glycosuria with no manifest diabetes. Scherf<sup>4</sup> found an even higher incidence, or six of nine cases. It would therefore be of interest to follow a larger series to determine just how often the condition does occur.

To my knowledge, Levine<sup>5</sup> in 1929 first called attention to this clinical finding, and it has since been referred to by such authors as Cruickshank,<sup>6</sup> Edelmann,<sup>3</sup> Scherf,<sup>4</sup>

Gottsegen<sup>7</sup> and Raab and Rabinowitz.<sup>8</sup> It did not become of serious consequence to the patient, however, until the advent of insulin, which agent, although being of life-saving therapeutics to the patient with true diabetes, has undoubtedly meant death to many persons suffering with acute coronary occlusion. Gigon<sup>9</sup> in 1923 first reported the death, after the administration of three doses of insulin, of a diabetic patient suffering with acute congestive heart failure. Nicely and Edmondson<sup>10</sup> concluded after clinical experience with two cases that myocardial incompetence had resulted from undernutrition of the heart muscle due to the lack of a reserve of cardiac and muscle glycogen. Recently it has been shown that there are definite electrocardiographic changes produced by insulin administration, the most consistent of them being a flattening of the T waves, particularly in lead I. Other changes noted with less frequency are delayed auriculoventricular conduction time, depression of the P waves and slurring and prolongation of the QRS complex.<sup>11</sup> These changes have not as yet been adequately explained. Many have thought them due solely to a hypoglycemic state, but von Haynal, Vidovszky and Györgi<sup>11</sup> give strong evidence in favor of a direct action of insulin on the heart muscle. Soskin and his co-workers,<sup>1</sup> on the other hand, have been able to produce practically identical electrocardiographic changes by merely keeping a diabetic patient with cardiovascular disease on a low carbohydrate diet with no insulin and practically no change in the blood sugar level noted. They conclude thereby that the etiologic agent is probably a lack of available carbohydrate for adequate cardiac nutrition.

That a high level of blood sugar is not deleterious but rather advantageous to the cardiac patient, particularly in the anginal type of cardiac distress, has been the clinical experience of many. Büdingen<sup>12</sup> in 1923 and Smith, Gibson and Ross<sup>13</sup> in 1927 have stressed the beneficial effects of the administration of dextrose and high carbohydrate diets in the relief of congestive heart failure.

As to the cause of the rise in the blood sugar, no one can at this time definitely say, although many theories have been advanced.<sup>8</sup> Whether it is a physiologic or a pathologic response has not been determined. The analogous occurrence of hyperglycemia and glycosuria in patients suffering with circulatory shock following cerebral hemorrhage, embolism and thrombosis may aid in the future in solving this problem. What is known, however, is that in a certain percentage of patients suffering with acute coronary occlusion such a phenomenon does occur and that when it is seen one must remember that it does not necessarily indicate any true diabetic state, that it will usually subside of its own accord, and that the employment of insulin is usually not necessary.

many plasma cells. The myocardium contained small recent hemorrhages. The bone marrow of the femur was 32 per cent cellular and showed 1.7 per cent myeloblasts, 51.6 per cent neutrophilic myelocytes, 2.6 per cent neutrophilic leukocytes, 0.5 per cent eosinophilic myelocytes, 1.5 per cent eosinophilic leukocytes, 0.7 per cent erythrogonias, 3.8 per cent erythroblasts, 13.3 per cent normoblasts, 0.5 per cent lymphocytes, 4.1 per cent plasma cells, 0.7 per cent monocytes and 0.4 per cent megakaryocytes.

## COMMENT

Comparing the extensive lymphocytic infiltrations with the diffuse fibrosis of the thyroid gland, it becomes evident that the two conditions represent different stages of the same process and that the lymphocytic infiltrations terminate in the replacement of the parenchyma by a dense and sclerotic connective tissue. As far as the lymphocytic infiltrations are concerned, it appears to me that they are exaggerated forms of the interstitial nodular accumulations of lymphocytes which are so commonly found in exophthalmic goiters and in simple goiters and which are also occasionally observed

Fig. 3 (case 2).—Section of thyroid. Bundles of coarse connective tissue fibers enclosing degenerating epithelial cells. (Paraffin section; van Gieson stain; magnification 150 diameters.)

in normal thyroids, particularly in elderly and obese women (Simmonds,<sup>14</sup> Wegelin<sup>12</sup>). It is now generally assumed that the interstitial lymphocytic nodules result from the excessive resorption of the secretion products of the follicles or form about follicles that undergo degeneration or involution. They are secondary phenomena that can be linked to degeneration, involution, hypoplasia or functional disturbance of the gland (Wegelin,<sup>12</sup> Graham and McCullagh,<sup>1</sup> Williamson and Pearse,<sup>15</sup> Goormaghtigh,<sup>16</sup> Connor<sup>17</sup> and others). In the most pronounced cases they replace most of the parenchyma. Among the factors that may cause degeneration of the thyroid, infections have often been referred to; and, in the history of the cases presenting chronic thyroiditis, Riedel's goiter and Hashimoto's

goiter infections, especially of the respiratory tract, have repeatedly been stressed. One of my patients with fibrosis of the thyroid had suffered from frequent colds. The case presenting the most extensive lymphocytic infiltrations of the thyroid showed a combination with syphilitic aortitis and meningo-encephalitis. Of the twenty cases of fibrous atrophy of the thyroid described by Simmonds,<sup>18</sup> four were associated with an old syphilis, and the observations of the Monods<sup>19</sup> and Küttner<sup>20</sup> seem to indicate that syphilis may be responsible for sclerosis of the thyroid. Roulet<sup>21</sup> describes an obliterating endophlebitis and endarteritis in Riedel's goiter which resembles the vascular changes observed in syphilis, but he does not consider them as indicating the syphilitic origin of the thyroid lesions. In my case the process in the thyroid did not carry the histologic earmarks of a syphilitic inflammation and did not differ from the changes in the other cases in which there were no evidences of syphilis. I believe that any infection may lead to nonspecific degenerative changes of the thyroid gland with a secondary lymphatic reaction and that those glands are predisposed to degeneration which are either hypoplastic or are the site of a pathologic or physiologic involution. It is this predisposing involution which may account for the fact that the disease under discussion affects mainly women after the menopause. In none of my cases were there any indications that the administration of iodine might be connected with the process.

Because of the intimate relations between the glands of internal secretion, one may expect that the grave alteration of the thyroid affects also the other endocrine glands. Histologically there were no evidences of involvement of the parathyroids, adrenals, hypophysis or pineal glands or of the islands of the pancreas in the cases in which all these glands could be examined. This observation confirms the statement that the lymphocytic infiltrations and fibrosis of the thyroid, which is often found in Addison's disease, particularly the type that is due to the cytotoxic atrophy of the suprarenal cortex, is not secondary to the destruction of the adrenal cortex but is a separate although probably coordinate process (Brenner,<sup>22</sup> Dubois,<sup>23</sup> Köhler,<sup>24</sup> Kreibitz,<sup>25</sup> Saphir and Binswanger,<sup>26</sup> Schmidt,<sup>27</sup> Shaw and Smith,<sup>11</sup> Weller,<sup>28</sup> Wells<sup>29</sup>). In my material of autopsies of the last eight years there were eleven cases of Addison's disease, four of which showed a cytotoxic atrophy of the adrenal cortex and seven of which were due to a fibrocaceous tuberculosis of the adrenal. ## SUMMARY

1. A patient suffering with acute coronary occlusion had transitory hyperglycemia and glycosuria.

2. Hyperglycemia and glycosuria are common to the syndrome of acute coronary occlusion, as is borne out by the study of a series of seventy-four cases.

3. Such clinical changes are usually of a transitory nature and do not necessarily indicate any true diabetic state.

4. A high level of blood sugar is beneficial rather than harmful in acute cardiac patients, as is evidenced in the literature.

5. The employment of insulin in the therapy of such cases is usually not necessary and, if undertaken, must be done with caution.

HYPERSENSITIVITY TO ACETYL-  
SALICYLIC ACID (ASPIRIN)

LOUIS E. PRICKMAN, M.D.

AND

HAROLD F. BUCHSTEIN, M.D.

Fellow in Neurosurgery, the Mayo Foundation  
ROCHESTER, MINN.

Among the most dramatic and dangerous manifestations of allergy are those reactions which occur following the ingestion, by hypersensitive individuals, of familiar and ordinarily innocuous drugs. Such reactions not only may defeat the purpose for which the drug was administered but may produce a new train of distressing symptoms and, in extreme cases, may lead to death. Hypersensitivity to drugs of all types has been recognized for a long time and reports of reactions from even the newest drugs follow closely on their introduction into common use. It is to be expected, therefore, that hypersensitivity to acetylsalicylic acid (aspirin), because of the frequent and promiscuous use of this drug, would be relatively more frequent than hypersensitivity to other drugs. Our experience as well as that of others<sup>1</sup> bears this out.

This report is based on a review of the literature and a study of sixty-two cases of true hypersensitivity to acetylsalicylic acid from the records of the Mayo Clinic. Cases of poisoning from acetylsalicylic acid, such as those reported recently by Dyke<sup>2</sup> and by Neale,<sup>3</sup> are not under consideration here since the condition in those cases was the result of overdosage rather than of specific hypersensitivity. For purposes of comparison we have summarized a series of thirty-three cases of hypersensitivity to acetylsalicylic acid reported in the literature. This by no means represents the total number of cases reported but merely those concerning which enough detail was given to render them suitable for tabulation. Even so, this series is not strictly comparable with ours, for many of the reports are incomplete and many of the authors were concerned with but a single phase of hypersensitivity to acetylsalicylic acid.

The earliest report we have encountered was that of Hirschberg,<sup>4</sup> who in 1902 observed a case of urticaria

and purpura following the ingestion of 1 Gm. of acetylsalicylic acid. He had no conception of allergic diseases as they are thought of today, but he did compare the reaction with some he had observed following the use of quinine and antipyrine. Most of the remaining articles are reports of small series or isolated cases. No one apparently has attempted to survey the field as a whole.

## THE GROUP AS A WHOLE

*Incidence.*—We have no knowledge of the incidence of hypersensitivity to acetylsalicylic acid in the general population. Most cases undoubtedly go undiagnosed or unreported. It is significant that during recent years, while our threshold of suspicion of sensitivity to acetylsalicylic acid has been relatively low, the frequency with which the diagnosis is made has been increasing. The actual incidence probably is much higher than ordinarily supposed. "Aspirin sensitivity," stated Coca,<sup>1</sup> "is the commonest form of drug hypersensitivity encountered in atopy." It likewise has been recognized that hypersensitivity to acetylsalicylic acid, or aspirin, is particularly common among asthmatic patients. Giving 5 grains (0.3 Gm.) of acetylsalicylic acid to each of 100 asthmatic patients, van Leeuwen<sup>5</sup> noted reactions in sixteen. He felt, however, that this figure was too high for general application, as sensitivity to acetylsalicylic acid is more common among patients with severe asthma. Van Leeuwen estimated, therefore, that about 10 per cent of all asthmatic persons are specifically allergic to acetylsalicylic acid and that the percentage is even greater among those who have severe asthma. Our impression clinically is that this estimate is entirely too high for the group of asthmatic patients encountered in this country. We feel that the incidence is much higher than is generally supposed, however, as can be demonstrated by routine questioning of allergic patients with reference to sensitivity to drugs.

*Sex.*—There is a definite preponderance of females in the group of patients hypersensitive to acetylsalicylic acid. Among our patients the ratio was forty females to twenty-two males. In the cases assembled from the literature the ratio was nineteen females to fourteen males. Although we have no data on this point, we believe this difference to be an expression of the greater tendency on the part of women to resort to the use of anodynes rather than an expression of any specific difference in the sexes.

*Age.*—At the time of registration at the Mayo Clinic, two thirds of our patients were between 31 and 50 years of age; 90 per cent were between the ages of 21 and 60 years. Cases from the literature show a similar distribution.

*Age at Onset.*—Of greater interest, however, is the age at which the first symptoms of hypersensitivity to acetylsalicylic acid were observed. One patient was but 10 years old; another had reached the age of 64 years. Approximately two thirds of the group were between 21 and 50 years. Thus, sensitivity to acetylsalicylic acid is prone to appear in individuals of middle age, at a somewhat later age than is characteristic of the onset of most allergic diseases.

*Familial and Personal History of Allergy.*—Of forty-six patients interrogated, thirty-two (78 per cent) gave a definitely positive history of allergic phenomena

No special attention has so far been paid to the blood changes in cases presenting Riedel's or Hashimoto's goiter. My three cases in which lymphocytic infiltrations of the thyroid was an incidental finding did not show any unusual changes of the blood. The case presenting myxedema showed a lowered hemoglobin content but the number of the red blood cells was normal. In one of the cases of advanced fibrotic atrophy of the thyroid a marked, slightly hypochromic anemia was present, which remained constant until the patient died. The bone marrow was active and there were no evidences of a disturbed differentiation or maturation of the cells of the bone marrow. The cause of the anemia is therefore difficult to determine from the anatomic changes. The presence of iron in the spleen and liver may be due to an excessive destruction of the erythrocytes or to the failure of utilizing the iron. In the other case of sclerosis of the thyroid the anemia was very severe and of the aplastic type and the histologic picture of the bone marrow fitted well with an aplastic anemia. This case also presented a lobar pneumonia, and the plasma-cellular-lymphocytic reaction of the bone marrow, spleen and lymph nodes can be attributed to the complicating infection.

It is, of course, not permissible to draw conclusions from two isolated observations. The two cases suggest, however, that in unexplained anemias of elderly women the possibility of a grave alteration of the thyroid gland should be taken into consideration even though the cases do not present manifestations of myxedema. Unfortunately, determinations of the basal metabolic rate were not made in my cases. Whether the anemia is directly related to the lack of the thyroid hormones or merely a part of the diminished vitality of all the tissues I do not venture to decide.

#### SUMMARY

Four cases of extensive lymphocytic infiltration of the thyroid gland, which closely resembles the histologic picture of Hashimoto's goiter, emphasize that this infiltration may not cause an enlargement of the gland. In three of the cases the infiltration was an incidental finding while in the fourth case it was associated with myxedema.

531 Grant Place.

#### ABSTRACT OF DISCUSSION

DR. LINDON SEED, Chicago: In view of the relation of anemia to myxedema, the medical department of the University of Illinois requested a total thyroidectomy in a patient with polycythemia vera. At present, nine months since thyroidectomy, she has a total myxedema. The blood volume, which was elevated, has been depressed, but the red blood count is the same as before operation. As time passes anemia may appear; for the present at least there has been little effect. There is a type of Riedel's struma that begins with soreness in the neck, slightly elevated temperature, leukocytosis and an elevated basal metabolic rate with its secondary manifestations. I have operated on three such patients and the microscopic picture was that of a typical woody thyroiditis with giant cells. In spite of the temperature elevation, tissue cultures were negative. In one patient there was an associated syphilitic aortitis, nephritis and hypertension. It was obvious that she would not live long. I did a biopsy on the right lobe and at autopsy three months later obtained the left lobe. To my surprise the left lobe showed good thyroid follicles and much less fibrosis. Apparently with passage of time the condition improved. In view of this it seemed to me that, unless there was obstructive dyspnea, one could leave the thyroid alone. In three successive cases I did so, and the patients recovered nicely. Unfortunately, however, the fourth one, who had what I thought was a Riedel's struma, went to another physician who did a biopsy and proved it to

be an adenocarcinoma. Such a mistake is too easy to make and one is not justified in treating the condition without a biopsy.

DR. LEON ASHER, Berne, Switzerland: I should like to remark on the possible relationship between the thyroid gland and anemia. That there may be such a relationship can be definitely shown by physiologic methods. There is no doubt that the bone marrow is under the regulating influence of the thyroid gland. That can be tested with functional methods. For instance, regarding the behavior of leukocytes, if a normal animal is injected with 2 per cent of sodium salt of nucleic acid there will be an enormous increase of leukocytes, and a pathologist or anatomist will easily demonstrate an increased activity of the bone marrow. If the thyroid gland is removed, this reaction will not appear any more as long as one does not give senseless amounts of sodium nucleic acid. There are various experimental proofs that the bone marrow is under the regulatory influence of the thyroid gland as to red blood corpuscles and white corpuscles. Cases must always be analyzed. Why is there a special, more outspoken anemia in certain types of thyroid disease, a certain deficiency of the internal secretion? There may be something else besides. I have reference to the spleen with its inhibitory regulating influence on the bone marrow. There may be cases in which, in addition to the deficiency of the thyroid gland, there is added the inhibitory influence of the spleen, resulting in more pronounced diminution of the functional capacity of the bone marrow. If the spleen is removed, the function of the bone marrow returns. There is certainly a regulatory augmentory influence of the thyroid and bone marrow and an inhibitory one of the spleen. The real function of the thyroid is the regulation of permeability. One can show in animals and in human beings the decreased permeability of cells and blood vessels and the decreased interchange between blood vessels and cells, so that, if myxedema exists in certain cases, something else must enter besides. What that something else is, the physiologist cannot tell. That is the business especially of experimental pathologists and physicians. Let them find the reason why in certain cases there is myxedema and in certain cases not. I can only say that if one observes the patients in my country one will see in some most exquisite myxedema and in others none.

DR. ANTON J. CARLSON, Chicago: Complete thyroidectomy in the experimental animal leads to anemia. This is not new. The anemia comes on gradually. The difficulty of recognizing myxedema lies mainly in that we have in our mind's eye the picture of advanced myxedema, while neither in the laboratory nor in the clinic are there sufficiently delicate methods to determine the beginning stages, particularly in cases in which one does not follow the basal metabolic rate. Certainly in the rabbit, in which one can in most cases make a total thyroidectomy, there are a lowered basal rate, anemia, a lowered temperature, changes in the skin and interference with hair growth, all the characteristics that go with myxedema. But these develop gradually. I certainly could not recognize the initial stage at present. I have some respect for a Boston bean, particularly if it isn't baked, and if it contains thyroid tissue, because I have seen great hypertrophy or hyperplasia of thyroid remnants that were not even the size of a Boston bean or even of a mustard seed. Man is not so different from other mammals, in which there may be accessory thyroids from the base of the tongue to the base of the heart. Hence one can seldom be certain that total thyroidectomy has been achieved. I am intrigued by the report of the rejuvenating effect on women beyond 45 by taking out thyroids that are degenerated to start with. If the facts are as reported the thyroidectomy can have nothing to do with it. It must be the proximity of the surgeon.

DR. RICHARD H. JAFFÉ, Chicago: I am grateful to Dr. Carlson and Dr. Asher for discussing my paper. I enjoyed the witty remarks also. What I wanted to emphasize is the fact that hypofunction of the thyroid may present itself occasionally under the clinical picture of a severe blood dyscrasia. I am aware of the possibility that if in the cases which I described pathologically a hypofunction of the thyroid had been suspected clinically, other evidences of this hypofunction might have been detected. In these cases one may speak of a "masked myxedema." I hope that my presentation may have stimulated investigative work into the nature of the obscure anemia, especially those of elderly women.

among their blood relatives. Fourteen did not have knowledge of any such familial tendency. An almost identical incidence of familial allergy, twelve (80 per cent) out of fifteen, was noted by Cooke<sup>6</sup> in a group of patients sensitive to drugs. On the other hand, van Leeuwen concluded that most individuals who are allergic to acetylsalicylic acid have no hereditary allergic background, a conclusion that is contradicted by our observations.

Most of the patients allergic to acetylsalicylic acid whose cases are reported in the literature were sufferers from some allergic disease, most frequently asthma. All but three of our patients had or had had one or more allergic disorders in addition to their hypersensitivity to acetylsalicylic acid. Of these three, two gave a positive familial history of allergy. It seems very significant, therefore, that all but one patient in a group of sixty-two gave a positive familial or personal history of allergy. This finding reemphasizes<sup>7</sup> the potential danger from the indiscriminate use of drugs in cases in which there is evidence of major allergic disease. No more convincing argument against the use of acetylsalicylic acid as a remedy for asthma is needed except

to point out, as we do later in this article, the cases of death resulting from its use by asthmatic patients.

It is hardly necessary for us to point out that the value of acetylsalicylic acid as a drug is not being questioned. It would seem that nonallergic individuals need have little or no concern about experiencing from the ingestion of this drug the reactions that are described in this paper. The fundamental difficulty in cases of hypersensitivity to the drug lies not in the drug itself but in the individual who ingests it.

It is interesting to note that not one of our patients came to the clinic primarily because of hypersensitivity to acetylsalicylic acid. A great majority, however, came with or because of some allergic complaint, and such complaints usually were multiple. Forty-three patients had had asthma, thus illustrating the frequent relationship between the two disorders. Twenty-one had vasomotor rhinitis, eleven had hay fever, and ten gave a history of urticaria or angioneurotic edema. Six patients were subject to migraine. Four patients of the group had sinusitis, and twenty-one were found to have nasal polyps.

*Features of the Allergic Reaction to Acetylsalicylic Acid.*—The administration of a tablet of acetylsalicylic acid to one of these hypersensitive individuals may

result in one or several different allergic reactions. Practically all the commonly accepted major allergic syndromes except eczema were encountered in our series. The respiratory mucous membrane is by far the most frequently reacting tissue; the skin, subcutaneous tissues and blood vessels next, and the gastro-intestinal tract next. A summary of the reactions of our patients to the administration of acetylsalicylic acid is given in the table.

It is interesting to note that the reaction which follows the ingestion of acetylsalicylic acid is usually, although not necessarily, an exacerbation of the patient's allergic disease. We have observed cases of vasomotor rhinitis in which asthmatic attacks were experienced following the taking of acetylsalicylic acid and others in which giant urticaria developed but in neither of which instances was any aggravation of nasal symptoms experienced. Such cases, however, are the exception rather than the rule.

*Speed of Reaction.*—The time intervening between the administration of acetylsalicylic acid and the onset of symptoms usually is short, the minimal recorded time being ten minutes and the longest two hours. This is so striking that it would seem that symptoms occurring at an interval longer than two hours, or at the most three hours, after the ingestion of acetylsalicylic acid are probably not due to true allergic sensitivity to the drug. "Delayed" reactions were not encountered in our series. Two patients (3 per cent) stated that their symptoms (asthma) occurred "almost immediately" after taking acetylsalicylic acid. Thirty patients (48 per cent) stated that their reaction occurred within one hour or less, and four (6 per cent) stated that their symptoms occurred in from one to two hours. The average recorded interval was thirty-two minutes. The reports in the literature agree closely with our experience. In Cooke's series the symptoms began from fifteen to twenty minutes after the ingestion of acetylsalicylic acid.

The speed of reaction varied considerably with the type of reaction. For instance, the average interval between the ingestion of acetylsalicylic acid and the onset of asthma in twenty-three cases was twenty-five minutes. Vasomotor rhinitis appeared in one case ten minutes after the taking of acetylsalicylic acid. Eight patients had hives on the average of fifty minutes after taking the drug. Three patients experienced abdominal cramps on the average of sixty-five minutes after ingesting it. The explanation for this variation in the interval before a reaction developed is not at once apparent.

*Eosinophils and Sedimentation Rate.*—Differential blood counts were not made as a routine in our series of cases. Six differential counts were made for as many individuals: Two showed an absence of eosinophils; three, 2 per cent of eosinophils, and one, 9 per cent of eosinophils. Cooke found an increase of eosinophils of from 10 to 15 per cent in "practically all" his cases in which sensitiveness to antipyretics was present. Van Niekirk<sup>8</sup> found that the sedimentation rate of erythrocytes is normal in cases of asthma but greatly accelerated in cases of asthma in which hypersensitiveness to acetylsalicylic acid is shown. We have no data on this point.

*Types of Reaction.*—Asthma: This is at once the most frequent and most serious form of reaction to

6. Cooke, R. A.: Allergy in Drug Idiosyncrasy, J. A. M. A. 73: 759-760 (Sept. 6) 1919.

7. Duke, W. W.: Aspirin Allergy: A Method of Testing for Aspirin Sensitiveness and Method of Avoiding Aspirin Catastrophes, J. Allergy 4: 426-427 (July) 1935. Coca.<sup>3</sup>

8. Van Niekirk, quoted by van Leeuwen.<sup>24</sup>

in a boiling water bath, filtered, and the whole amount injected into a dog that had been previously standardized with regard to its sensitivity.

The material produced an increase of 2.84 mg. per hundred cubic centimeters of blood calcium, whereas, in the same animal, 300 units of parathyroid extract obtained from normal beef parathyroid glands treated in the same way had previously produced an increase of 5.04 mg. per hundred cubic centimeters of blood calcium. This material was equivalent, therefore, to approximately 169 units (Hanson) of parathyroid extract. On this basis, the entire adenoma contained approximately 275 units, or slightly more than 105 units per gram. This is about

Fig. 3.—Cell arrangement and sparseness of stroma of parathyroid adenoma.

twice the amount of parathyroid hormone per gram obtained from normal beef parathyroid gland.

**Postoperative Course of the Patient.**—Two hours after operation and twice daily subsequently the patient was given 20 cc. of 10 per cent calcium gluconate solution intravenously and 1 cc. of parathyroid extract<sup>5</sup> hypodermically. Her serum calcium nevertheless dropped from a preoperative level of 11.2 mg. to 9 mg. per hundred cubic centimeters in twenty-four hours and reached 7.9 mg. on the third postoperative day. There were no obvious signs of tetany. On a low phosphorus diet<sup>6</sup> with added viosterol (30 drops daily) and calcium gluconate tablets (276 grains [18 Gm.] daily) orally her serum calcium level gradually rose and reached 10.3 mg. per hundred cubic centimeters exactly one month after operation. She felt stronger and brighter daily and ate with unusually good appetite. Her anemia responded to iron and liver therapy with addition of hydrochloric acid. Renal function improved, and the blood urea nitrogen fell to 16.0 mg. per hundred cubic centimeters with rising urinary output. Roentgen examination of the abdomen showed no evidence of calcareous deposits in the region of the kidneys. One month after operation it was possible to discontinue parathyroid injections. Three months after operation she was discharged in good condition. When seen at home (March 21, 1936) she was no longer wearing a cast, her muscle function was improved, and she was walking about her room. Her anemia was much less (hemoglobin 75 per cent, erythrocytes 3,820,000), and on a normal diet which included one quart of milk daily her serum calcium was 9.7 mg. per hundred cubic centimeters and phosphorus 3.4 mg. per hundred cubic centimeters. July 7, 1936 (eight months after parathyroidectomy) her blood serum calcium was 10.1 mg. per hundred cubic centimeters and the serum phosphatase had become normal (12 units).

#### SUMMARY

In a typical case of hyperparathyroidism marked clinical improvement resulted from surgical excision of an adenoma of

5. Parathyroid extract-Squibb. One unit (Hanson) is defined as one one hundredth of the amount of extract required to cause an increase of 1 mg. of calcium per hundred cubic centimeters of blood serum in dogs weighing from 10 to 12 Kg., the increase being determined after subcutaneous administration to dogs of a sufficient quantity of solution to cause an average increase in blood serum calcium of from 4 to 6 mg. within sixteen hours. One cubic centimeter contains 100 units.

6. Shelling, D. H., and Goodman, M. J.: Calcium and Phosphorus Studies. IX. The Importance of Low Dietary Phosphorus in the Treatment of Parathyroid Tetany. J. A. M. A. 102:669 (March 3) 1934.

the left lower parathyroid gland. Bio-assay of the gland revealed approximately 105 units of hormone per gram. Search of the literature reveals no previous instance in which direct analysis was made of the hormone content of such an adenoma.

#### PIGMENTATION OF THE SKIN DUE TO IRON (COPPERAS) APPLIED LOCALLY

RICHARD L. SUTTON JR., M.D., KANSAS CITY, MO.

There are several cases on record of pigmentation following the local application of iron-containing medicinal substances. One may well take warning from these that the use of certain agents is liable to be followed by discoloration, which may be permanent.

#### REPORT OF CASE

Miss G. H., a robust woman, aged 33, with blue eyes, dark hair and brunette skin of fine texture, contracted impetigo, which commenced with "blisters" on her neck, June 13, 1936. For five days she applied tincture of iodine several times a day, without benefit. Then, at the suggestion of a neighbor, she made up a strong solution of copperas, which is ferrous sulfate,  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ , a translucent, greenish crystalline substance known also as green vitriol. She did not measure the strength, simply dissolving several teaspoonfuls in a glass of water. She applied the solution by "dabbing it on several times a day for two or three days." The condition became worse and pained her severely. She then used magnesium sulfate solution for a short time, without benefit. June 23 she was seen at the dispensary of the University of Kansas Hospital, where a saturated solution of lead acetate was prescribed. On applying this, she said her face burned violently and felt "cooked," and the lesions became darker and redder. Then 10 per cent ammoniated mercurial ointment was prescribed, and on June 30 notable improvement was observed along with a red-brown pigmentation of the lesions. It was surmised this would go away, but it did not do so. August 11 she returned to the

Brown pigmentation at the sites of healed lesions of impetigo. The discoloration is due to the use of a copperas solution (ferrous sulfate) followed by lead acetate solution, with the resulting staining of the skin with basic ferric acetate.

dispensary to learn whether or not something might be done to hasten the disappearance of the discoloration. A 2 per cent solution of salicylic acid in 30 per cent alcohol was given her but yielded no effectual results. Then the area was blistered with ultraviolet rays, with no greater benefit.

I obtained this information from the patient and from the records September 30, at which time she presented the striking appearance that the illustration shows. From a distance one would jump to the conclusion that she had impetigo, but the

polychromatic macrocytes. Platelets were practically absent. The clinical diagnosis was aplastic anemia. Three days after admission the patient died.

**Autopsy.**—The body weighed 62 Kg. and the body length was 160 cm. There was a lobar pneumonia in the stage of brown hepatization of the left lower pulmonary lobe. Petechial hemorrhages were found in the skin and in the mucosa of the renal pelvis and urinary bladder. In the left rectus abdominis muscle and in the retroperitoneal tissue large extravasations of blood were present. The heart weighed 450 Gm. and the leaflets of the aortic valve were slightly deformed. The intima of the aorta and coronary arteries was smooth. The liver weighed 1,825 Gm., the spleen 175 Gm. and the kidneys 475 Gm. The gallbladder contained a single cholesterol stone. The internal genitalia were atrophic and the ovaries showed small follicular cysts. The adrenals were very soft and their cortex was a light yellow. The thyroid weighed 22 Gm. It was of normal shape, felt very firm and consisted of light pinkish brown tissue (fig. 1). The brain could not be examined.

**Microscopic Examination.**—In place of the normal thyroid tissue there was a dense fibrillar connective tissue, which was loosely infiltrated by lymphocytes, plasma cells and histiocytes. In focal areas the lymphocytes accumulated to small nodules, in the region of which a delicate, argentaflavine reticulum could be demonstrated. These nodules enclosed the residues of disintegrated follicles. The colloid had disappeared and the epithelial cells were swollen and finely vacuolated. Their nuclei were shrunken and crenated (fig. 2). In van Gieson stained sections, isolated groups of vacuolated epithelial cells could be seen between the coarse connective tissue fibers (fig. 3). There were small nests of polygonal cells with ample cytoplasm and vesicular nuclei, which were surrounded by a layer of argentaflavine fibrils in the same manner as the follicles of the thyroid.<sup>13</sup> The wall of the arterioles and small arteries was slightly thickened, the intima of the larger arteries was moderately thickened and the internal elastic membrane was calcified.

The bone marrow was 17.8 per cent cellular and the cellular areas were composed of 52.2 per cent plasma cells, 38.3 per cent lymphocytes, 3 per cent monocytes, 4.3 per cent normoblasts, 1.1 per cent basophilic granulated cells, 0.4 per cent neutrophilic myelocytes, 0.4 per cent eosinophilic myelocytes and 0.3 per cent eosinophilic leukocytes. The plasma cells were large, and many of them contained from two to four nuclei. Similar to the bone marrow the lymph nodes and the spleen showed numerous large and often multinucleated plasma cells, and plasma cells could also be seen in the lumen of the portal sinusoids of the liver. There was much iron pigment in the spleen but none in the liver. The liver showed centrilobular, focal necrosis and a swelling and proliferation of the Kupffer cells. The alveolar exudate of the lung consisted of compact casts of fibrin with very few mononuclear cells. There were focal areas of necrosis, and the branches of the pulmonary artery leading to these areas of necrosis were occluded by fibrin thrombi. There was a slight increase of the interlobular fat tissue of the pancreas, and the islands were well preserved. The parathyroids contained the number of interstitial fat cells that corresponded to the age of the patient. Clear chief cells predominated. The lipid content of the adrenal cortex was much reduced and in the fascicular zone there were small nests of plasma cells, lymphocytes and iron filled histiocytes. The hypophysis could not be examined, since permission for removing the skull was not obtained.

**CASE 3.—History.**—A white American woman, aged 63, complained of extreme weakness, which had developed within the last six months. For the past month she had been eating very little because of a sore tongue. Recently she suffered from a severe diarrhea.

**Examination.**—On admission her temperature was 98.5 F., her blood pressure 78 systolic, 65 diastolic, the pulse rate 104 and the respiratory rate 16. The eyes were sunken, the tongue was coated, its edges were injected and there was also an injection of the mucosa of the soft palate and the pharynx. The neck, lungs and heart did not show any abnormalities. The Wassermann and Kahn tests of the blood gave negative results. The examination of the urine was negative, as was also the examination of the feces.

Examination of the blood showed a hemoglobin content of 57 per cent. It decreased later to 48 per cent. The number of erythrocytes decreased from 2,980,000 to 2,580,000, and the number of the white cells varied between 5,750 and 10,500. There were from 71 to 81 per cent neutrophils, from 9 to 19 per cent lymphocytes, from 4 to 10 per cent monocytes and an occasional eosinophilic and basophilic leukocyte. There was a slight anisocytosis of the erythrocytes and a shifting of the neutrophils to the left. The platelet count was 200,000.

The patient was given a high vitamin diet and liver extract but she failed to respond. Because of her extreme weakness, no satisfactory determination of the basal metabolic rate could be made. The final diagnosis was anemia, probably of endocrine nature, most likely Simmonds' disease. She died six weeks after admission to the hospital.

**Autopsy.**—The body weight was 45 Kg. and the body length was 160 cm. In the skin of the neck and the dorsal aspect of the left forearm, single, up to 15 mm., confluent, dark purple red patches were seen. The right lung showed focal areas of consolidation. The heart weighed 285 Gm., the liver 1,230 Gm.,

Fig. 2 (case 2).—Section of thyroid. Lymphocytic nodule containing the residue of a follicle, which is composed of finely vacuolated epithelial cells with crenated nuclei. (Paraffin section; hemalum-eosin; magnification 150 diameters.)

the spleen 60 Gm. and the adrenals 12 Gm. The hypophysis measured 20 by 14 by 5 cm. The weight of the thyroid amounted to 9 Gm. The organ was of normal shape and of firm consistency and was made up of homogeneous pale gray tissue. There was a slight atheroma of the coronary arteries and a more marked atheroma of the abdominal aorta. The brain weighed 1,250 Gm.

**Microscopic Examination.**—The thyroid resembled closely that of the preceding case. Again the diffuse, sclerosing fibrosis was the outstanding feature. Lymphocytic nodules and residues of follicles were less conspicuous than in case 2. There were small groups of squamous epithelial cells (fig. 4). In the anterior lobe of the hypophysis the oxyphilic cells predominated, and there were many small follicles filled with a colloid-like substance. The intermediary part consisted of several large, colloid-filled follicles. The posterior lobe, adjacent to the intermediary part, showed single, small nests of oxyphilic cells with eccentrically placed and deeply stained nuclei. The cortical cells of the adrenal contained much lipid material and there were small cortical adenomas, which were rich in fat. The parathyroids contained many fat cells and the clear chief cells predominated. The pineal gland consisted of islands of moderately sized cells with round or slightly indented nuclei. The ovaries were atrophic. The liver and the spleen showed a very marked hemosiderosis and in the pulp of the spleen there were

13. The metaplasia of the epithelium of the thyroid will be discussed in a separate paper.

There are nevertheless a great many institutions that have no photographic facilities, and here the physician is thrown on his own resources whenever photographic recording is necessary. Furthermore, in his private practice the practitioner may find it expedient to photograph his own material, especially when much photography is to be done or when transitory pathologic conditions make an immediate photograph necessary.

Some mention has been made in medical literature of the possibilities of clinical photography,<sup>1</sup> but for the most part the literature on medical photography is addressed largely to those who are already acquainted with the fundamentals of photographic technic. This fact has undoubtedly contributed to the prevailing misconceptions that the technic of medical photography is difficult and the necessary apparatus inordinately expensive. The rise of the miniature camera, too, has created the attitude among many practitioners that less expensive cameras are useless so far as clinical photography is concerned. Yet perfectly satisfactory work may be done with inexpensive cameras, and many physicians who possess folding roll film cameras are able with the addition of a few bits of supplementary apparatus to obtain splendid results in all branches of macrophotography, photomicrography, the photography of necropsy and biopsy specimens, copying work, enlarging, and even color and infra-red photography. The present article deals with the practical aspects of clinical photography and outlines a minimum of apparatus necessary for work in the various fields. Only such photographic theory has been introduced as is absolutely essential to an understanding of practical principles.

#### THE CHOICE OF A CAMERA

*Plate and Film Pack Folding Cameras.*—The most satisfactory camera for clinical use is a folding plate and film pack camera equipped with a double extension bellows and a ground glass back. The wide variety of photographic emulsions available in plates, cut films and film packs satisfies all requirements of latitude, speed, contrast, fineness of grain and color sensitivity. The double extension bellows permits the full-scale copying of charts, pictures and diagrams and is useful in photomicrography. The ground glass back allows critical focusing. The camera furthermore may be used as the principal part of an enlarging or projecting apparatus. The most satisfactory picture size is either  $2\frac{1}{4}$  by  $3\frac{1}{4}$  inches or  $3\frac{1}{4}$  by  $4\frac{1}{4}$  inches, from which a suitable contact print may be obtained if an enlargement is not desired.

*Reflex Cameras.*—The chief advantage of reflex cameras is that the focus can be adjusted up to the instant of exposure. This advantage is offset by the bulk and cost of the camera. For clinical purposes the focal plane shutter with which the reflex cameras are equipped is not as suitable as the ordinary "between-the-lens" shutter, since the slower speeds, from one-fifth second to 1 second, cannot be obtained. Folding patterns of the reflex camera have been devised, but these are somewhat more difficult to manipulate than the box reflex type. Double lens reflex cameras overcome the ordinary disadvantages of the reflex camera, being compact and allowing the slower speeds, but are rather costly and there is some error in parallax on extreme closeups.

*Miniature Cameras.*—Although considered a toy by many photographers, the miniature camera is rapidly gaining in popularity and promises to become the universal camera of the future. Precision instruments, such as the Leica and Contax, are supplied with fine optical equipment and combine sturdiness of construction, compactness, speed, and ease of operation. The film used is a fine grain cine-negative film of standard 35 mm. width, from which enlargements of many diameters may be obtained. The small size and light weight of the camera permit it to be carried in a coat pocket, and the high speed lens equipment allows satisfactory exposures under unfavorable light conditions. The relative inexpensiveness of movie film is another factor to be considered, especially when many pictures are to be taken or when color photographs are desired. Furthermore, positive film transparencies may be made for projection purposes at a great saving as compared to the cost of lantern slides. There are, however, several disadvantages associated with the miniature camera. The price of a precision camera with the highest speed lens amounts to several hundred dollars, but this initial price is tremendously augmented by the cost of supplementary apparatus, such as equipment for copying, enlarging and microscopic work, without which satisfactory clinical photography cannot be done. Miniature films require more meticulous handling than larger films, the slightest errors in processing rendering good enlargements impossible. Another objection is that contact prints are too small for detail to be readily seen; consequently all pictures must be enlarged, a fact that destroys the operating economy. The average spool of film used contains thirty-six exposures and this is another serious drawback, since it is necessary to expose the entire roll before any single desired negative can be obtained. Miniature roll film cameras that take sixteen pictures on ordinary vest pocket roll film are less expensive but lack some of the important features of the precision instruments.

*Roll Film Cameras.*—With the wide range of emulsions available in roll film, perfectly satisfactory results in clinical photography may be achieved by employing a good roll film camera. Two essentials are necessary: first, a reliable anastigmatic lens; second, a shutter with slow speeds of one-fifth to 1 second. Supplementary portrait and copying lenses will substitute satisfactorily for the double extension bellows, and reasonably sharp focus may be obtained by measuring by rule the distance between the subject and the camera. Photomicrographic work may be accomplished with ease, and the camera may be used for enlarging or projecting purposes. There are many good inexpensive roll film cameras with these features available.

*Lenses.*—Standard cameras are usually equipped with reliable anastigmatic lenses corrected for astigmatism, chromatism and spherical aberration. The quality of a lens is difficult to estimate without actual trial, but a lens manufactured by a reputable maker will ordinarily prove satisfactory. Cooke, Zeiss, Ilex, Schneider, Leitz, Goerz, Voigtlander, Bausch and Lomb, and Meyer lenses rank among the best. For pleasing perspective the focal length of the lens should be equal to or greater than the diagonal of the film or plate. The speed of the lens depends, of course, on the maximum aperture, and rarely, except in the miniature cameras, is it advisable to purchase a lens with a speed greater than  $f/3.5$ , faster lenses for larger cameras being bulky, expensive, and providing very small depth of

two cases of cytotoxic atrophy of the adrenal cortex the thyroid was densely infiltrated by lymphocytes, while in one the infiltrations were insignificant and in one case absent. Two cases of fibrocasseous tuberculosis of the adrenal showed much lymphocytic infiltration of the thyroid. In one case the infiltrations were of moderate intensity and in three cases of mild intensity, and in one case the thyroid was unchanged. In a Negro woman, aged 29, with Simmonds' disease, in whom the anterior lobe of the hypophysis had been completely replaced by scar tissue, the thyroid was atrophic, weighing 10 Gm., but was free from lymphocytic infiltrations. The adrenals weighed 6.5 Gm. and the inner layer of the fascicular zone and the reticular zone had been transformed into dense connective tissue. In another case in which the anterior lobe of the hypophysis had been destroyed by a fibrocasseous tubercle, thyroid and adrenals were unchanged. These cases indicate that the combination of pathologic changes of the glands of internal secretion does not follow any definite rule and that all possible combinations may occur. In polyglandular insufficiency the thyroid, however, is almost constantly involved and often seems to form the center of the symptom complex.

With regard to the marked anemia in the two cases of sclerosis of the thyroid gland, the question may be raised whether this anemia is related to the lesion of the thyroid or is coincidental. The influence of the thyroid on the bone marrow has been the subject of many clinical and experimental studies, of which I mention only some of the more recent ones. Schwanke<sup>30</sup> found that three fifths of his cases of exophthalmic goiter showed a polycythemia with erythrocyte counts between 5 and 8.6 million. Improvement was frequently followed by a drop in the number of the erythrocytes. Schermann<sup>31</sup> noticed an increased reticulocyte count among the population of the endemic goiter district of Mari (Russia). A series of papers deals with the anemia in myxedema (Emery,<sup>32</sup> Lerman and Means,<sup>33</sup> Stone,<sup>34</sup> Mackenzie,<sup>35</sup> Boros and Czoniczner<sup>36</sup> and others). Boros and Czoniczner<sup>36</sup> studied the blood picture in twelve cases of myxedema and found in five cases a macrocytic anemia and in one case a normocytic anemia. Lerman and Means<sup>33</sup> pointed out that anemia is more common in the patients with myxedema and gastric anacidity than in the patients with myxedema and free hydrochloric acid in the gastric juice. The combination of myxedema with true pernicious anemia has been described by Means, Lerman and Castle,<sup>37</sup> Giffin and Bowler,<sup>38</sup> Davis,<sup>39</sup> Boros and Czoniczner<sup>36</sup> and Holbøll.<sup>40</sup> In uncomplicated pernicious anemia the basal metabolic rate is increased, while it is lowered in the cases presenting pernicious anemia and myxedema.

Mendershausen<sup>41</sup> has stressed that the thyroid of patients with pernicious anemia is often atrophic and infiltrated by lymphocytes, an observation which I have not been able to confirm. Heilmeyer and Albus<sup>42</sup> described a severe hemolytic anemia that developed from a myxedema anemia following grip and was complicated by acromegalic symptoms. The autopsy of this case revealed a complete atrophy of the thyroid. One of the cases of Riedel's goiter reported by Boyden and his associates<sup>5</sup> terminated fatally two years after the operation from pernicious anemia and cirrhosis of the liver. In a case of severe nonhemolytic anemia with hepatosplenomegaly and advanced sclerotic atrophy of the thyroid and positive serologic reaction for syphilis, Serio<sup>43</sup> is inclined to consider a simultaneous syphilitic alteration of the spleen, the liver, the thyroid and the blood-forming tissues.

Fig. 4 (case 3).—Section of thyroid. Small nests of squamous epithelial cells surrounded by dense connective tissue and loose accumulations of round cells. (Frozen section; hematoxylin-eosin stain; magnification 150 diameters.)

Sharpe and Bisgard<sup>44</sup> and others have found that complete removal of the thyroid in young rabbits causes a moderate macrocytic anemia, which becomes fixed at a certain level and then remains constant. Kunde, Green and Burns<sup>45</sup> observed a macrocytic anemia in thyroidectomized rabbits. Latta and Benner<sup>46</sup> found that thyroxine injected into albino rats produced a rise in the percentage of the reticulocytes, which in some instances was later followed by a decrease. The bone marrow, in particular the erythropoietic tissue, was hyperplastic. After large amounts of thyroxine there were evidences of exhaustion of the bone marrow.

**Washing and Drying.**—Washing should be carried out for approximately one hour in running water to remove all traces of hypo. The films should be moved about freely, but excessive handling must be avoided to prevent scratching the emulsion. On being removed from the washing tank, the film is wiped with a damp chamois or damp cotton to remove excess water and then is hung up to dry. An electric fan will promote rapid drying.

**Reducing and Intensifying.**—In instances of incorrect exposure or development, negatives may be either too dense or too thin to print well. Such negatives may sometimes be salvaged by the use of reducing and intensifying solutions. Heavy overexposed negatives are best treated by Farmer's reducer,<sup>3</sup> which is a cutting reducer tending to increase contrast. For overdeveloped negatives a permanganate proportional reducer<sup>3</sup> which lowers contrast should be used.

Intensifying solutions<sup>3</sup> will increase the printing density of thin, flat negatives, but markedly underexposed negatives that have little detail will not benefit much by intensification.

**Printing.**—The materials needed for making contact prints are few and consist of a printing frame, rubber squeegee, developing-out paper, a few enameled ferrotype tins, and a suitable safelight. To give the best rendering of fine detail, a paper with a glossy surface such as Glossy Velox or Azo is recommended. It is available in six degrees of contrast to compensate the variation in the printing quality of negatives. The negative is placed in the printing frame emulsion side upward, and the paper is placed on the negative emulsion side downward. The back of the frame is replaced and the paper is exposed to white electric light. The exposure time required depends on the density of the negative, the contrast of the paper and the intensity of white light. A 25 watt or 40 watt bulb may be used as a light source and a few trials will indicate the correct exposure. M. Q. tube developer solution or D-72 developer<sup>3</sup> will be found satisfactory. The acid short-stop bath and fixing bath are identical to those used for negatives. Following a wash of one hour in running water, the prints are squeegeed face downward on the ferrotype tins, which have been prepared by polishing with a glazing polish. A good polish may be made by dissolving a small amount of paraffin in benzene.

**Positive Film Transparencies.**—For exhibition purposes, photographs may be printed on Eastman Process Safety Film, the film being used in the same manner as developing-out paper. Exposure and development are carried out the same as for paper. The positive prints may be framed in cardboard mounts and a piece of Eastman Acetate Sheeting or cellophane may be placed over the emulsion side of the print in order to protect it. The detail apparent in positive prints is splendid when viewed through an illuminator. Reversible movie film may be obtained for use in miniature cameras, the negative being converted directly into positive prints for projection purposes. A better method, however, is to employ the regular negatives and print them on positive movie film in order to preserve the negative in case other positive photographs are desired.

**Retouching.**—Being accurate scientific records, negatives obviously cannot be retouched. It is permissible, however, to block out backgrounds and extraneous subjects with an opaque substance such as Eastman Opaque. Numbers and indications may be drawn on

the negative with the opaque material, and in the final print or enlargement these will show up as white marks.

**Enlarging.**—Briefly stated, the process of enlarging consists of placing a negative between a concentrated source of light and a lens, and focusing the image on a piece of bromide paper, which is processed in the usual manner. Enlarging machines may be purchased in vertical types, which focus on a table, or in horizontal types, which utilize an upright screen for focusing purposes. Enlarging is facilitated in vertical machines, but enlargements of more than six to ten diameters are more difficult to obtain than in horizontal enlargers.

With a little ingenuity any camera equipped with a good anastigmatic lens and removable back may be adapted for an enlarger. A light-proof box, from 8 to 12 inches square, is painted white on the inside, and to one wall there is attached a socket to hold a Photo-flood bulb. An opening is cut in the opposite wall somewhat larger than the size of the negative to be used. A piece of opal glass, to serve as a diffuser of light, is placed on the inside of the box over this opening. On either side of the opening on the outside of the box there is attached a grooved vertical strip of wood to act as a guide for the negative carrier, which may be an ordinary printing frame with the back removed or two pieces of thin, good quality glass, between which the negative is sandwiched. Metal or cardboard masks may be purchased or constructed to shield negatives of various sizes. An air vent must be constructed on top of the box to permit the escape of heat without allowing the escape of light. For this purpose several tin cans of unequal size, painted dead black, may be utilized, the smaller cans being placed within the larger and the bottoms perforated in different positions so that the light cannot shine through directly. The back of the camera is removed and the camera placed snugly against the window of the box. The negative carrier containing the mask and negative is inserted between the box and camera within the two grooved strips of wood. The light is turned on and the image focused sharply on a screen by moving the lens board of the camera backward or forward. The size of the image and therefore the degree of enlargement is controlled by varying the distance between the lens and the screen.

A convenient paper holder may be constructed from a stiff piece of cardboard by gluing four art corners, such as are used in mounting pictures in albums, on the cardboard in such a position that the bromide paper may be easily introduced and removed. Either the screen or the table on which the enlarger rests must be movable in order to obtain varying degrees of enlargement. In the latter case the wall of the room may be utilized as a screen.

In making enlargements, a darkroom illuminated by an orange safelight is necessary. The image is focused on the cardboard paper holder, which is affixed to the screen by several pushpins. The light in the enlarger is turned off and a piece of bromide paper is introduced into the paper holder. The light is then turned on again for the necessary exposure. A few trials with small strips of bromide paper will indicate the correct exposure to use.

The exposed bromide paper is placed in the developer, acid short-stop, and fixing solution in the same manner as in the processing of contact prints. For developer solution M. Q. tubes, D-72 developer or the formula

## Clinical Notes, Suggestions and New Instruments

### BIO-ASSAY OF A PARATHYROID ADENOMA IN A CASE OF GENERALIZED OSTEITIS FIBROSA

SYLVAN E. MOOLTEN, M.D., NEW YORK

FRANCIS M. CLARKE, M.D., AND HENRY HAYWOOD, M.D.  
NEW BRUNSWICK, N. J.

The evolution of the concept of hyperparathyroidism may be traced in successive stages from the original description of osteitis fibrosa cystica by von Recklinghausen<sup>1</sup> to its emergence as a disorder of function of the parathyroid glands, culminating in Mandl's<sup>2</sup> important observation that removal of a parathyroid adenoma resulted in marked immediate clinical improvement of the condition. The chain of evidence at present is almost complete that excessive secretion of parathyroid hormone by such an adenoma is to be regarded as the essential cause of the bony changes, hypercalcemia, and associated phenomena of this disease.<sup>3</sup> Reports in the available literature, however, contain no instances in which the actual hormone content of adenomas removed surgically has been determined.

Removal of a parathyroid adenoma in the following case permitted a biologic assay of its hormone content:

#### REPORT OF CASE

**History.**—A woman, aged 42, was admitted to St. Peter's Hospital, Oct. 25, 1935, for treatment of fractures of the humerus and femur. For at least six years she had had "rheumatic pains" in her limbs, polydipsia, polyuria and noc-

Fig. 1.—Marked osteoporosis and fibrocystic changes in humerus with fractures.

turia. Four months before admission, while pushing a trunk, she fell and injured her hip. Roentgen examination on the day of admission to the hospital showed evidence of advanced cystic disease and osteoporosis of the bones with fractures of

the humerus and femur (fig. 1). The diagnosis of hyperparathyroidism was made by the roentgenologist, Dr. William Klein. The blood serum calcium was 12.3 mg. per hundred cubic centimeters, phosphorus 2.8 mg., and the phosphatase was elevated to 39.4 King-Armstrong units. Urinalysis revealed calcium phosphate and triple phosphate sediments, slight albuminuria, occasional leukocytes, and fixation of the specific gravity between 1.010 and 1.012. Blood urea nitrogen was 21.5 mg. per hundred cubic centimeters, and the phenolsulfonphthalein excretion in the urine only 12 to 17 per cent in two hours. The hemoglobin was 44 per cent (Dare) and erythrocytes 3,540,000, with hypochromia and slight basophilic stippling. Fractional gastric analysis (Rehfuß) revealed complete absence of free hydrochloric acid and a total acidity of 30. Immobilization and moderate traction were applied for the fractures (Dr. Haywood). Two weeks after admission the patient was operated on for suspected parathyroid adenoma.

**Operation (Dr. Clarke).**—Under tribrom-ethanol anesthesia with procaine hydrochloride infiltration the thyroid was exposed; two normal parathyroids were identified on the right side. A large, yellowish, encapsulated body, the size of a small olive, was found without difficulty lying flush with the anterior surface of the lower pole of the left lobe of the thyroid within a common sheath. The mass was easily liberated from a smooth fibrous bed within the thyroid gland. A frozen section was reported "parathyroid adenoma."

**Description of the Specimen.**—The gland tissue removed at operation weighed 2.6 Gm. It formed a single mass with slight lobulation (fig. 2). The cut surface was uniform and solid, without visible finer structure or obvious fibrosis or cyst formation, light amber in color, and having a soaplike homogeneity of aspect. Part of the gland was reserved for histologic study and the remainder, weighing 1.6 Gm., was placed on ice for twenty-four hours. It was then chopped fine and transferred to acetone and sent to Dr. J. A. Morrell of the Biological Laboratories of E. R. Squibb & Sons, through whose kindness the assay for hormone was effected.

**Microscopic Examination.**—The cells of the gland were arranged compactly in curving rows and rounded nests, often forming small acini (fig. 3). A few acini possessed a small round or oval clear lumen. The individual cell groups and acini were separated by a delicate stroma of exceedingly narrow connective tissue fibrils with wide or narrow capillary vessels. The uniformly solid glandular appearance of the tissue was interrupted in a few places by venous sinuses and a few coarser fibrous trabeculae from which the finer network arose. Nearly all the cells were of one type corresponding to the transitional oxyphil cell.<sup>4</sup> The cell borders were usually distinct and clearly defined the shape of the cells as rounded, cuboidal or polygonal, varying considerably in size. Often the cell boundaries were indistinct. The cytoplasm was finely granular and compact, and stained a faint pink with hematoxylin and eosin. The nuclei were generally rounded with a tendency to polygonal shape, and ranged in size from 7 to 12 microns or even larger. The larger nuclei showed dense chromatin masses, the smaller nuclei a more evenly distributed lighter chromatin with tiny nucleoli. No mitoses were seen. A few groups of cells occurred the cytoplasm of which had been largely replaced by large clear spaces in which the nuclei appeared as if suspended (wasserhelle, or clear principal cells).

The diagnosis was transitional oxyphil cell adenoma.

**Results of Bio-Assay (Dr. J. A. Morrell).**—Defatting and desiccation of the tissue were completed by the use of acetone and the residue was then completely dried. The dried glandular material was then heated with 3 per cent hydrochloric acid

the camera. A cardboard screen is held in front of the first lamp to cast a shadow on the ear, which will add contour to the face. A similar type of uneven lighting may be used in subjects when it is desired to emphasize contours.

The Photoflash lamp is a special type of bulb containing aluminum foil and oxygen, producing a brief blue-white light of great intensity when connected to a flashlight battery or ordinary 115 volt house circuit. The flash is one-fiftieth second, and snapshots may be made in cases of weak or nervous subjects who cannot hold still for time exposures. The intensity of illumination makes it possible to utilize small shutter openings, thus increasing the depth of field and rendering detail sharp in various planes. The time of posing is reduced to a minimum, and there is no time lost in arranging lights; consequently pictures may be taken in places where it is impossible to obtain conveniently proper illumination. To some physicians photography by means of the Photoflash lamp method will prove itself ideal to the exclusion of other illuminants. Two white portable reflectors, such as white window shades, mounted on stands placed on each side of the subject, will intensify and more evenly distribute the light. A conical reflector for the lamp similar to the Photoflood reflector is necessary to concentrate the light. The only disadvantage is the cost, since only one picture can be made with each lamp. However, when it is considered that retakes because of movement of the patient are practically eliminated, the actual cost per successful picture compares favorably with other methods of illumination.

*Exposure.*—After the patient has been posed in front of the background with the part to be photographed illuminated to best advantage, the camera mounted on a tripod is focused carefully on the subject. The distance from the subject to the camera must correspond exactly to the distance scale set on the camera. Failure to measure the distance accurately is responsible for the majority of out-of-focus pictures. Measurements must be made with a tape measure from the center of the lesion or part to be photographed to the lens of the camera. This is especially important in cameras not equipped with a ground glass focusing back. Cameras without a double extension bellows cannot be moved closer to the subject than 4 or 5 feet; consequently when the pathologic lesion or subject is small, it may be expedient to use a portrait attachment over the regular lens. It is usually advisable to photograph according to a definite scale. Some cameras, such as the Eastman Clinical camera; are equipped with a focusing scale which makes it easy to obtain identical areas in all photographs made. A good substitute for a focusing scale is to record the distance between the subject and the lens and to make subsequent photographs at the same distance.

The exposure is dependent on the intensity of light, lens aperture, and speed of the photographic emulsion used. The closer the lamps are moved to the subject, the greater the concentration of light and the less the exposure. Since in many instances the subject cannot be kept quiet, shutter speeds slower than one twenty-fifth second will result in a blurred picture. By using the same film and the same number of Photoflood bulbs at the same distance from the subject, exposures can easily be standardized by the physician and good results uniformly obtained. The wider apertures  $f/4.5$ ,  $f/5.6$

and  $f/6.3$  will generally be found necessary for snapshots, but if the character of the picture is such as to necessitate sharpness of detail over a considerable area, greater depth of field will be obtained with the smaller apertures  $f/8$ ,  $f/11$ ,  $f/16$  and  $f/22$ , and the exposure can be increased or the intensity of the light strengthened either by bringing the lamps closer to the subject or by employing more lamps. While a good exposure meter will undoubtedly prove itself invaluable, simple experimentation will teach one the proper exposure times to employ. As a general rule two Photoflood bulbs in a reflector at a distance of 4 feet from the subject will allow, with the fastest films and apertures of from  $f/4.5$  to  $f/6.3$ , an exposure of one twenty-fifth second. Each lens stop as denoted by  $f$ /numbers necessitates twice the exposure required when the next larger stop is used. Thus, in the series  $f/4$ ,  $f/5.6$ ,  $f/8$ ,  $f/11$ ,  $f/16$ ,  $f/22$  and  $f/32$ , each successive stop will require twice the exposure of the one preceding.

In utilizing Photoflash lamps the subject is posed against the background and, if possible, white reflectors are arranged on each side of the subject. The camera, mounted on a tripod, is placed at a distance corresponding to the distance scale on the camera, and, if the camera has a ground glass back, focusing is accomplished by means of a Photoflood lamp. The Photoflash lamp is placed to the right of the camera so that a line drawn from the lamp to the subject forms with the axis of the camera a 30 to 45 degree angle. The extraneous lights in the room are turned off, the shutter of the camera, which has been set on Time, is opened, and the Photoflash lamp fired by turning on the switch, and finally the shutter of the camera is closed. With a No. 10 Photoflash lamp 3 feet from the subject, the diaphragm opening should be  $f/22$ ; at 4 feet the opening should be  $f/16$ ; at 9 feet,  $f/11$ . If expense is no object a Photoflash Synchronizer, such as is used by press photographers, may be purchased. This Synchronizer both operates the shutter of the camera and fires the Photoflash lamp.

*Photographic Emulsions.*—For all-round work a rapid orthochromatic material, such as Eastman Super Speed Ortho Portrait Safety Cut Film or, in roll film, Verichrome film will yield good results. Being insensitive to red, the orthochromatic materials register skin lesions and blemishes accurately without a filter. Panchromatic and supersensitive panchromatic emulsions may be used for speed work, and Eastman Portrait Panchromatic Cut Film, Wratten Hyper Sensitive Panchromatic Plate, and Kodak Super Sensitive Panchromatic Roll Film and Filmpack are popular materials of this type. In order to standardize results, one type of film or plate should be used until the capacities of that particular emulsion are fully understood. In using panchromatic emulsions it will be necessary to use a contrast filter, such as Wratten B green filter, for the purpose of accentuating reddish skin lesions. The exposure must, of course, be increased to compensate for the associated filter factor. Sometimes a Wratten C blue filter will accentuate a lesion better than the green filter. For accurate monochromatic rendering of a subject with panchromatic film, the  $X_1$  or  $X_2$  filter may be employed. Whenever extreme enlargements are contemplated, the use of a fine grain orthochromatic material or panchromatic emulsion, as Eastman Panchromatic film, is advisable.

(To be continued)

skin was entirely free from inflammation and had been so for six weeks. The lesions were macular, without any change in texture whatever, and entirely without symptoms excepting unsightliness. The pigment appeared to be superficially located but was not in the epidermis, as was proved by the therapeutic failure of ultraviolet irradiation in blistering dosage. The red-brown sepia was deeper at the periphery of the circular, annular and crescentic lesions that were formerly impetiginous. The shading reduplicated the appearance of active impetigo.

There had occurred, she said, some slight paling of the lesions during the time they had existed. It was judged unwise to attempt their removal by various means of irritation, and, *faute de mieux*, a cosmetic preparation was prescribed, to the considerable satisfaction of the patient.

## COMMENT

The pigmentation is understood with the following chemical explanation, for which I am in part indebted to Miss Elizabeth Bachman. Ferrous sulfate is a powerful astringent. Applied to the oozing impetiginous lesions, the iron attached itself to the superficial connective tissue of the dermis. Ferrous valence was soon oxidized to ferric. The tissue fluid maintained a faintly alkaline state. Lead acetate was applied, with the production of insoluble basic ferric acetate, which possesses the exact red-brown color that the patient presented.

Basic ferric acetate is used commercially for the purpose of dyeing silk, wool and other materials this particular color. The patient's dermis could not have been more satisfactorily stained by a professional industrial chemist. How long the pigmentation will persist is in doubt. It has faded a little, and, since iron is susceptible of being utilized in the body, it may be eventually absorbed. An effort to peel away the marks is futile. They might be removed by shaving off the superficial layers of the corium, as Dubreuilh<sup>1</sup> has done in order to eradicate tattooing, but the likelihood of scarring is great.

Pigmentation due to iron, such as is reported here, has been recorded by Pusey,<sup>2</sup> who observed permanent punctate staining of the skin following the application of a copperas solution prescribed for the relief of an oozing dermatitis. Lead acetate solution had been used before the copperas. Pusey's histologic investigation revealed that the iron was distributed in amorphous granules, which, unstained, were light brown and reacted with potassium ferricyanide to form deep blue grains. These were unevenly scattered in collections of variable size between the connective tissue fibers in the subpapillary layer of the corium and were separated from the superimposed normal-appearing epidermis by an unstained but thin connective tissue zone. They were both intracellular and extracellular. Some fibers seemed to have been converted into granules. Pusey attributed the pigmentation to iron hydroxide.

Traub and Tennen<sup>3</sup> recorded two cases of similar staining due to a ferric chloride solution used to treat dermatitis from poison ivy. They reviewed the literature with regard to the use of iron salts for the condition, a form of therapy which, introduced by McNair<sup>4</sup> in 1921, has been of considerable popularity. "Many have attested the usefulness, harmlessness and efficacy of preparations of iron salts in both the treatment and the prophylaxis of rhus poisoning." They list articles over a decade from various journals; yet only half a dozen or so cases of permanent pigmentation have been recorded.

The inference is evident that there is more involved than the mere application of ferrous sulfate or ferric chloride to the denuded skin if pigmentation is to be produced.

The explanation lies, I believe, in that it is the acetate of iron which dyes the dermis. Unless the iron is applied while or before an acetate is present, it is harmless. Certainly more cases of pigmentation would have been observed if iron salts alone were responsible. It is not unusual that lead acetate or aluminum acetate is employed to alleviate a moist dermatitis such as ivy causes. It is true that iron salts in the presence of

acetate stain various materials such as silk, a protein from a chemical standpoint not greatly unlike the collagenous tissue of the skin. The case which I report stands in evidence that iron did not cause pigmentation until acetate was applied. It is a reasonable presumption that the rare cases of iron pigmentation are due to the coincidental use of the other agent.

Traub and Tennen did not state that acetate had been used previous to the application of iron in either of their patients, but they did not state that it had not. Their patient had been treated with calamine lotion, a weakly alkaline mixture containing zinc carbonate. Perhaps other agents than acetate will likewise enable iron to fix itself permanently to the protein molecule. Iron-containing lotions must not be prescribed when acetate is also being used; and acetate lotions must be scrupulously avoided if iron has been used.

## SUMMARY

Permanent reddish brown pigmentation of the skin at the sites of lesions of impetigo was caused by the use of a solution of copperas (ferrous sulfate) followed by the application of a solution of lead acetate.

Pigmentation in this case is due to the dyeing of the corium with basic ferric acetate.

Iron solutions are commonly used to treat oozing dermatoses without resultant discoloration. Ferric acetate is used commercially to dye silk and other materials the reddish brown seen in this and similar cases, which are rare. It is probable that the rare cases of pigmentation following the use of iron solutions are cases in which acetate has been used coincidentally.

Such pigmentation when it occurs cannot be removed by peeling or irritative therapeutic measures, for the iron deposits are not in the epidermis. It can be removed only by procedures that are likely to scar. With certain cosmetic preparations, it can be hidden successfully.

### PRACTICAL CLINICAL PHOTOGRAPHY

LEWIS R. WOLBERG, M.D.  
KINGS PARK, N. Y.

The scientific and medicolegal advantages of photographic case records are apparent to most physicians, although relatively few physicians take the opportunity of utilizing their clinical material for photographic purposes. There is scarcely a specialty or branch of experimental and clinical medicine and surgery which cannot be enriched by photography. Dermatologic lesions, neoplasms, developmental and nutritive disorders, deformities, neurologic disturbances, fractures, dislocations, burns, inflammations and a host of other conditions lend themselves readily to photographic recording. The photography of surgical instruments, appliances and special apparatus, the recording of operative procedures, the reproduction of gross and microscopic necropsy and biopsy specimens, blood, parasitologic and bacteriologic specimens, the copying of charts, records and roentgenograms and the making of lantern slides and transparencies for teaching purposes are other accomplishments that the camera makes possible.

The Biological Photographic Association, organized for the purpose of fostering cooperation between the professional photographer and the private physician in the interest of better methods and results, has done much toward raising the standards of medical photography. An increasing number of physicians consequently are availing themselves of the services of professional photographers, and progressive institutions are developing well equipped photographic departments.
